ENCYCLOPÆDIA BRITANNICA.

ELEANOR, of Aquitaine (1122-1204), queen of France and afterwards of England, was the daughter of William IX., the last duke of Guienne, and was born in 1122. She succeeded her father in 1138, and was married the same year to Louis VII. of France. Her lively and somewhat frivolous manners, and her love of pleasure, did not fit her for the society of a husband who was naturally austere, and who from religious conviction had adopted many ascetic habits. They became gradually estranged, and in the Holy Land, whither she had accompanied Louis in 1147, their quarrels became so frequent and so bitter that at last a divorce was agreed upon, which on their return from France was completed under the pretext of kinship, 18th March, 1152. Six months afterwards she gave her hand and her possessions to Henry of Navarre, who in 1155 mounted the throne of England as Henry II. That the duchy of Guienne should thus become permanently annexed to the English crown was naturally displeasing to Louis, and the indirect consequence of his displeasure was protracted wars between France and England. In other respects also the marriage had unhappy consequences. The infidelities of Henry, and the special favors he showed to one of his mistresses, so greatly roused Eleanor's jealousy, that she incited her son Richard to rebellion, and also intrigued with her former husband to get him to lend his influence to the great league formed against Henry in 1173. Her son had fled to Louis, and she was preparing to follow him when she was arrested and placed in confinement, where she remained till the death of her husband in 1189. As soon as he died she regained her liberty, and reigned as regent until Richard's arrival from France. She also held this position during Richard's absence in the Holy Land, for which he left in 1190. After his escape in 1194 from the captivity which befell him as he was returning home, she retired to the abbey of Fontevrault, where she died April 1, 1204.

ELEATIC SCHOOL, a Greek school of philosophy, so called because Elea was the birth-place or residence of its chief representatives. Parmenides, who was born at Elea probably about the year 515, was the first completely to develop the Eleatic doctrines; but his philosophy has a very close connection with that of Xenophanes, who was born more than a century earlier. Xenophanes, indeed, has been described as the founder of the school, and though that title is with more strictness to be given to Parmenides, it may not incorrectly be applied to him. The philosophy of Xenophanes took its rise in a strong antagonism to the popular anthropomorphic mythology; and, though it contains part, it is far from containing the whole, of the Eleatic doctrine as maintained by Parmenides and his followers. Its chief doctrines were that "the One is God," and that God is self-existent, eternal, unchangeable, immovable, of the same substance throughout, and in every respect incomparable to man.

The Eleatic philosophy is founded upon the doctrine of a complete severance and opposition of thought and sense. Truth is in no degree attainable by sense; sense gives only false appearances, non-being: it is by thought alone that we arrive at the knowledge of being, at the great truth that "the All is One," eternal, unchangeable; or rather, as Hegel rightly interprets the Eleatics, thought *is* being. No distinction is drawn by Parmenides between thought and material being; the "One and All," indeed, is described materially as a perfect and immovable sphere. The notions of creation, change and destruction, diversity and multiplicity, time and space, and the various sensations, are all mere false appearances of sense, which thought shows to be contradictory and false. Upon a very common confusion of the word *exist* with the verb *to be*, which does not necessarily imply existence, he founded his argument against the possibility of creation: creation cannot be, for being cannot arise out of non-being; nor can non-being be. Again, there can be no difference or change except in appearance, for a thing cannot arise from what is different from it. But this side of the Eleatic argument was more completely developed by Zeno. In the second part of his poem, Parmenides, notwithstanding his assertion of their falseness, does offer an explanation of the facts of consciousness. Of this part of his theory, however, we have only very incomplete knowledge. It stands altogether distinct from his main doctrine. It is materialistic, like nearly all the other early Greek explanations of the universe. The universe (that is, the apparent universe) is, he says, made up of two elements, one of which he describes as heat and light, the other as cold and darkness. Of these elements all men are composed, and their thinking varies as the proportions in which these elements are mixed in their composition. Even the dead body feels cold and darkness.

Zeno, born in the beginning of the 2d century B.C., the fellow-townsman, disciple, and adopted son of Parmenides, is famous for his attempts to prove that the notions of time, space, motion, multiplicity, sight, sound, etc., are self-contradictory and unthinkable. His paradoxes were stated with a subtlety which has forced thinkers even of distinction, who were opposed to his main position, for instance, Sir William Hamilton, to admit some of them to be unanswerable. Against motion Zeno directed several arguments, the most celebrated being that of Achilles and the tortoise, which are founded upon the confusion of that which is infinitely divisible with that which is infinite. Against space Zeno argued that any space, however large, must be in a larger space, this larger space again in a still larger, and so on *ad infinitum.* Against the manifold he argued (1) that the manifold, being divisible into the infinitely small, *i.e.*, into that which has no magnitude, can itself have none, as divisions that have no magnitude must make up a whole without magnitude; and (2) that, being divisible into an infinite number of parts, it must be infinitely large. Against sound he argued—and he applied similar reasoning to sight—that, as you cannot hear a single grain of corn fall, you cannot hear the sound of a number of grains falling, the sound of the falling of the number of grains being made up of the sounds of the falling of each grain. Thus Zeno sought to prove that thought and sense are opposed, and that the latter, contradicting itself, proves itself unworthy of the consideration of the philosopher.

The last of the Eleatic teachers was Melissus of Samos, the friend of Heraclitus, who was probably born somewhat later than Zeno. We only possess fragments of his works, preserved by Simplicius and collected by Brandis. His modifications of the doctrines of his master, Parmenides, are not important, with the exception of his assertion of the infinity, the unlimitedness, of "the One and All," and his distinct insistance upon the doctrine that the "One and All" is immaterial, unextended, without parts.

See the separate articles XENOPHANES, PARMENIDES, and ZENO.

ELECAMPANE (M. Lat., *Enula Campana*), a perennial composite plant, the *Inula Helenium* of Linnæus, which is common in many parts of Britain, and ranges throughout central and southern Europe, and in Asia as far eastwards as the Himalayas. Its stem attains a height of from 3 to 5 feet; the leaves are serrate-dentate, the lower ones stalked, the rest embracing the stem; the flowers are yellow, and 2 inches broad, and have many rays, each three-notched at the extremity. The root, the *radix inulæ* of pharmacy, is thick, branching, and mucilaginous, and has a warm bitter taste and a camphoraceous odor. For medicinal purposes it should be procured from plants not more than two or three years old. Besides *inulin*, $C_{12}H_{20}O_{10}$, a body isomeric with starch, the root contains, according to Kallen, two crystallizable substances—*helenin*, C_6H_8O, and *alantcamphor*, $C_{10}H_{16}O$. By the ancients the root was employed both as a medicine and as a condiment, and in England it was formerly in great repute as an aromatic tonic and stimulant of the secretory organs. "The fresh roots of elecampane preserved with sugar, or made into a syrup or conserve," are recommended by Parkinson in his *Theatrum Botanicum* as "very effectual to warm a cold and windy stomack, and the pricking and stitches therein or in the sides caused by the Spleene, and to helpe the cough, shortnesse of breath, and wheesing in the Lungs." As a drug, however, the root is now seldom resorted to except in veterinary practice. In France and Switzerland it is used in the manufacture of absinthe.

ELECTIONS. The law of parliamentary and municipal elections in England is now governed as to procedure by the 35 and 36 Vict. c. 33 (the Ballot Act, 1872), and as to disputed returns by the 31 and 32 Vict. c. 125 (Parliamentary Elections Act, 1868) and 35 and 36 Vict. c. 60. See BALLOT and BRIBERY.

The inquiry into a disputed parliamentary election was formerly conducted before a committee of the House of Commons, chosen as nearly as possible from both sides of the House for that particular business. The decisions of these tribunals labored under the suspicion of being prompted by party feeling, and by the above-named Act of 1868 the jurisdiction was finally transferred to Her Majesty's judges, notwithstanding the general unwillingness of the bench to accept a class of business which they feared might bring their integrity into dispute. In future no election shall be questioned except in accordance with the provisions of this Act. Section 11 of the Act orders, *inter alia*, that the trial of every election petition shall be conducted before a *puisne judge* of one of the common law courts at Westminster and Dublin; that the said courts shall each select a judge to be placed on the *rota* for the trial of election petitions; that the said judges shall try petitions standing for trial according to seniority or otherwise, as they may agree; that the trial shall take place in the county or borough to which the petition refers, unless the court should think it desirable to hold it elsewhere. The judge shall determine "whether the member whose return is complained of, or any and what other person, was duly returned and elected, or whether the election was void," and shall certify his determination to the Speaker. When corrupt practices have been charged the judge shall also report (1) whether any such practice has been committed by or with the knowledge or consent of any candidate, and the nature thereof; (2) the names of persons proved to have been guilty of any corrupt practice; and (3) whether corrupt practices have extensively prevailed at the election.

Questions of law may be referred to the decision of the Court of Common Pleas. The report of the judge is equivalent to the report of an election committee under the old system. Petitions may be presented by the following persons:—(1) some person who has voted or had the right to vote at the election; (2) some person claiming to have a right to be returned or elected; (3) some person alleging himself to have been a candidate. The trial of a petition shall be proceeded with notwithstanding the acceptance by the respondent of an office of profit under the Crown, and notwithstanding the prorogation of Parliament; though it would appear that the dissolution of Parliament abates a petition. The judge appointed to try a petition shall be received with the same state as a judge of assize in an assize town. The costs and expenses of the petition shall be paid by the parties in such manner and such proportions as the court or judge may determine, regard being had to the discouragement of needless expense by throwing the burden thereof on the parties by whom it has been caused, whether they are on the whole successful or not. When a returning officer has wilfully neglected to return a person found on petition to have been entitled to be returned, such person may sue the officer (within one year of the act complained of, or six months of the trial of the petition), and shall recover double the damage he has actually sustained, together with full costs of suit.

To meet the additional work imposed on the English courts of common law by this act, power was given to appoint an additional judge to each of them. Section 58 applies the provisions of the Act, with certain modifications, to Scotland.

This, like the Ballot Act, is a continuing Act.

Petitions against municipal elections are dealt with in 35 and 36 Vict. c. 60. The election judges under the last described Act appoint a number of barristers, not exceeding five, to try such petitions. No barrister can be appointed who is of less than fifteen years' standing, or a member of Parliament, or holder of any office of profit (other than that of recorder) under the Crown; nor can any barrister try a petition in any borough in which he is recorder or in which he resides, or which is included in his circuit. The barrister sits without a jury. The provisions are generally similar to those relating to parliamentary elections in the former Act. The petition may allege that the election was avoided as to the borough or ward on the ground of general bribery, etc., or that the election of the person petitioned against was avoided by corrupt practices, or by personal disqualification, or that he had not the majority of lawful votes. And no election shall be questioned by any other process whatsoever for a matter for which it might have been questioned under this Act.

Introduction.

ELECTRICITY. The word *Electricity* is derived from the Greek word ἤλεκτρον, meaning *amber*. The term was invented by Gilbert,[1] who used it with reference to the attractions and repulsions excited by friction in certain bodies of which amber may be taken as the type. To the cause of these forces was given the name Electricity; and out of the study of these and kindred phenomena arose the science of electricity, of which it is the purpose of the present article to give a brief outline.

The science has been divided into three branches—*Electrostatics*, which deals with electricity at rest; *Electrokinetics*, which considers the passage of electricity from place to place; and *Electromagnetism*, which treats of the relation of electricity to magnetism. We shall, however, make no attempt to adhere to this division, but shall exhibit the different parts of the subject in such order and connection as seems most clear and natural in the present state of the science. For the sake of the non-scientific reader we prefix a brief history[2] of the science of electricity, wherein mention is made of some of the more striking electrical discoveries, and of the steps by which our knowledge of the subject has advanced to its present condition.

HISTORICAL SKETCH.

Thales, 600 B.C.

Animal Electricity.

The name of the philosopher who first observed that amber when rubbed possesses the property of attracting and repelling light bodies has not been handed down to our times. Thales of Miletus is said to have described this remarkable property, and both Theophrastus (321 B.C.) and Pliny (70 A.D.) mention the power of amber to attract straws and dry leaves. The same authors speak of the *lapis lyncurius*, which is supposed to be a mineral called *tourmaline*, as possessing the same property. The electricity of the torpedo was also known to the ancients. Pliny informs us, that when touched by a spear it paralyzes the muscles and arrests the feet, however swift; and Aristotle adds that it possesses the power of benumbing men, as well as the fishes which serve for its prey. The influence of electricity on the human body, and the electricity of the human body itself, were also known in ancient times. Anthero, a freedman of Tiberius, was cured of the gout by the shocks of the torpedo; and Wolimer, the king of the Goths, was able to emit sparks from his own body. 415 A.D. Eustathius, who records this fact, also states that a certain philosopher, while dressing and undressing, emitted occasionally sudden crackling sparks, while at other times flames blazed from him without burning his clothes. Such are the scanty gleanings of electrical knowledge which we derive from the ancient philosophy; and though several writers of the Middle Ages have made occasional references to these facts, and even attempted to speculate upon them, yet they added nothing to the science, and left an open field for the researches of modern philosophers.

---

[1] *De Magnete Magneticisque Corporibus.*

[2] A portion of this historical sketch was written by Sir David Brewster, and formed the introduction to his article "Electricity" in last edition of the *Encyclopædia*. It has been modified by suppressions and alterations here and there, and by large additions at the end which were thought necessary to make it suit the present state of science. For the sake of the student in search of original sources of information, pretty copious reference to such has been added throughout. Valuable for information of this kind the student will find Riess's *Reibungselectricität*, Young's *Natural Philosophy*, Wiedemann's *Galvanismus*, and the recent work on electricity by Prof. Mascart, of the Collége de France.

Gilbert (1540–1603). Dr. Gilbert of Colchester may be considered as the founder of the science, as he appears to have been the first philosopher who carefully repeated the observations of the ancients, and applied to them the principles of philosophical investigation. In order to determine if other bodies possessed the same property as amber, he balanced a light metallic needle on a pivot, and observed whether or not it was affected by causing the excited or rubbed body to approach to it. In this way he discovered that the following bodies possess the property of attracting light substances:—amber, gagates or jet, diamond, sapphire, carbuncle, rock-crystal, opal, amethyst, vincentina or Bristol stone, beryl, glass, paste for false gems, glass of antimony, slags, belemnites, sulphur, gum-mastic, sealing-wax of lac, hard resin, arsenic, rock salt, mica, and alum. These various bodies attracted, with different degrees of force, not only straws and light films, but likewise metals, stones, earths, wood, leaves, thick smoke, and all solid and fluid bodies. Among the substances which are not excited by friction Gilbert enumerated emerald, agate, carnelian, pearls, jasper, calcedony, alabaster, porphyry, coral, marble, Lydian stone, flints, hematites, smyris (emery or corundum), bones, ivory, hard woods, such as cedar, ebony, juniper, and cypress, metals, and natural magnets. Gilbert also discovered that the state of the atmosphere affects the production of electricity; dryness with north or east wind being a favorable condition, while moisture with south wind is unfavorable. An account of Gilbert's experiments will be found in his book *De Magnete*, lib. ii. cap. 2.

Boyle (1627–91). Robert Boyle added many new facts to the science of electricity, and he has given a full account of them in his *Experiments on the Origin of Electricity*. By means of a suspended needle, he discovered that amber retained its attractive virtue after the friction which excited it had ceased; and though smoothness of surface had been regarded as advantageous for excitation, yet he found a diamond which in its rough state exceeded all the polished ones and all the electrics which he had tried, having been able to move a needle three minutes after he had ceased to rub it. He found also that heat and *tersion* (or the cleaning or wiping of any body) increased its susceptibility of excitation; and that if the attracted body were fixed, and the attracting body movable, their mutual approach would still take place. To Gilbert's list of "electrics" Boyle added the resinous cake which remained after evaporating one-fourth part of good oil of turpentine, the dry mass which remains after distilling a mixture of petroleum and strong spirit of nitre, glass of lead, caput mortuum of amber, white sapphire, white amethyst, diaphanous ore of lead, carnelian, and a green stone supposed to be a sapphire.

Otto von Guericke (1602–86). To these discoveries of Boyle his contemporary Otto von Guericke added the highly important one of *electric light* (*Experimenta Nova Magdeburgica*, lib. iv. cap. 15). Having cast a globe of sulphur in a glass sphere, and broken off the glass, he mounted the sulphur ball upon a revolving axis, and excited it by the friction of the hand. By this means he discovered that light and sound accompanied strong electrical excitation, and he compares the light to that which is exhibited by breaking lump sugar in the dark. With this powerful apparatus Guericke verified on a greater scale the results obtained by his predecessors, and obtained several new ones of very considerable importance. He found that a light body, when once attracted by an excited electric, was repelled by it, and was incapable of a second attraction until it had been touched by some other body; and that light bodies suspended within the sphere of influence of an excited electric possessed the same properties as if they had been excited.

Newton (1643–1727). To our illustrious countryman Sir Isaac Newton the science of electricity owes some important observations. He used in his electrical experiments a globe of glass rubbed by the hand instead of the sulphur globe of Von Guericke. It would appear that Newton was the first to use *glass* in this way (*Optics*, query 8th). We owe also to Sir Isaac a beautiful experiment on the excitation of electricity which has since become very popular. Having fixed a round disc of glass in a short brass cylinder, he placed small pieces of thin paper within the cylinder and upon a table, so that the lower surface of the glass was one-eighth of an inch distant from the table. He then rubbed the upper surface of the glass, and he observed the pieces of paper "leap from one part of the glass to the other, and twirl about in the air." This experiment, after a previous unsuccessful trial, was repeated by the Royal Society in 1676 (Brewster's *Life of Newton*, p. 307).

Hawksbee, 1705. Francis Hawksbee, one of the most active experimental philosophers of his age, added many new facts to the science. In 1705 he communicated to the Royal Society several curious experiments on what he calls "the mercurial phosphorus." He showed that light could be produced by passing common air through mercury placed in a well-exhausted receiver. The air rushing through the mercury, blew it up against the sides of the glass that held it, "appearing all around like a body of fire, consisting of abundance of glowing globules." The phenomenon continued till the receiver was half full of air. These phenomena had been observed in the Torricellian vacuum before Hawksbee's time, and various explanations suggested. He suspected that they were due to electricity, and remarked their resemblance to lightning. Like Newton he used a revolving glass globe rubbed by the hand to generate electricity. Besides the experiment above alluded to he made many others on the electric light and on the attractions of electrified bodies. Descriptions of these will be found in his *Physico-Mechanical Experiments*, 1709, and in several memoirs in the *Philosophical Transactions* about 1707.

About the same time Dr. Wall (*Phil. Trans.*, 1708) observed the spark and crackling sound accompanying the electrical excitation of amber, and compared them to thunder and lightning.

Stephen Gray (1696–1736). One of the most ardent experimentalists of his time was Stephen Gray, a Fellow of the Royal Society. In his first paper, published in 1720, he showed that electricity could be excited by the friction of feathers, hair, silk, linen, woollen, paper, leather, wood, parchment, and gold-beaters' skin. Several of these bodies exhibited light in the dark, especially after they had been warmed; but all of them attracted light bodies, and sometimes at the distance of eight or ten inches. An epoch was made in the history of electricity by the discovery of Gray in 1729, that certain bodies had, while others had not, the power of conveying electricity from one body to another, *i. e.*, in modern phrase, *conducting* it. Gray experimented with a glass tube, into the ends of which were fastened two corks; into one of these he fastened a fir rod, and to the end of the rod an ivory ball. On rubbing the glass he found that the ball attracted the light bodies as vigorously as the glass itself. He made a variety of experiments with rods of different length, and with a packthread, by which he suspended his ball from the balcony of an upper story of his house, all with the same result. He then attempted to carry the electricity horizontally on a packthread which he suspended with hempen strings; but the experiment failed. On the occasion of a repetition of the experiments at the house of his friend Wheeler, silk strings were suggested as a support, and found to answer, while metal wires failed. Gray and Wheeler were thus led to the conclusion that it was the material of the supports that was in question, and that whereas packthread had, silk had not, the power of transmitting electricity to a distance. Gray and Wheeler managed, by supporting a packthread by silk loops, to convey electricity from a piece of rubbed glass to a distance of 886 feet. The conducting power of fluids, and of the human body, was established by Gray. He also made many curious experiments on the electrical properties of resinous cakes, which he allowed to cool and harden in the ladles in which they had been melted. For an account of these and others the student is referred to memoirs in the *Philosophical Transactions* for 1731, 1735, etc.

Desaguliers.

Desaguliers made many experiments confirming Gray's conclusions, and found that bodies that have the property of being electrically excitable by friction, or *electrics per se*, have not the power of *conduction;* whereas *conductors* are not *electrics per se.* These terms, introduced by him, were useful in bringing into concise and scientific language the discoveries of Gray.

Dufay (1699–1739).

While Gray was pursuing his career of discovery in England, M. Dufay, of the Academy of Sciences, and superintendent of the Royal Botanic Gardens, was actively employed in the same researches. He found that all bodies, whether solid or fluid, could be electrified by an excited tube, by setting them on a glass stand slightly warmed, or only dried; and that those bodies which are in themselves least electrical received the greatest degree of electricity from the approach of the glass tube. He repeated the experiments of Gray, confirming his results, and found that electricity was transmitted more easily along packthread when it was wetted, and that it might be supported upon glass tubes in place of silk lines. In this way he conveyed it along a string 1256 feet long. He suspended by silken strings and electrified a child as Gray had done; and having suspended himself in a similar manner, he discovered that an electrical spark, accompanied with a crackling noise, took place when any other person touched him, and he has described the prickling sensation like the burning from a spark of fire, which is at the same time felt either through the clothes or on the skin. The great discovery of Dufay, however, was that of two different kinds of electricity. He fully recognized the importance of this fundamental fact, and gave the name of *vitreous* electricity to that which is produced by exciting glass, rock-crystal, precious stones, hair of animals, wool, and many other bodies; and the name of *resinous* to that which is produced by exciting resinous bodies, such as amber, copal, gum-lac, silk, paper, thread, and a number of other substances. The characteristic of those two electricities was, that a body with vitreous electricity attracted all bodies with resinous electricity, and repelled all bodies with vitreous electricity; while a body with resinous electricity attracted all bodies with vitreous electricity, and repelled all bodies with resinous electricity. Two electrified silk threads, for example, repel each other, and also two electrified woollen threads, but an electrified silk thread will attract an electrified woollen thread. Hence it is easy to determine whether any body possesses vitreous or resinous electricity. If it *attracts* an electrified silk thread, its electricity will be vitreous; if it *repels* it, it will be resinous.

Vitreous and resinous electricity.

Gray repeated and varied the experiments of Dufay, and made many new ones. Like Hawksbee and Dr. Wall, he recognized the similarity between the phenomena of electricity, and those of thunder and lightning; and he expresses a hope "that there may be found out a way to collect a greater quantity of electric fire, and consequently to increase the force of that power, which, by several of these experiments, *si licet magnis componere parva,* seems to be *of the same nature with thunder and lightning.*"

Boze, Winkler, etc.

The discoveries which we have now recounted began to rouse the activity of the German and Dutch philosophers. To the electrical machine used by Newton and Hawksbee, Professor Boze of Wittenberg added the *prime* conductor, which at first consisted of an iron or tin tube supported by a man standing upon cakes of rosin; but it was afterwards suspended by silken strings. Professor Winkler of Leipsic substituted a *cushion* in place of the hand for exciting the revolving globe; and Professor Gordon of Erfurt, a Scotch Benedictine monk, first used a glass cylinder, eight inches long and four broad, which he caused to revolve by means of a bow and string. By these means, electrical sparks of great size and intensity were produced, and by their aid various combustible substances, both fluid and solid, were inflamed. In 1744, M. Ludolph of Berlin succeeded in firing, by the electrical spark, the ethereal spirit of Frobenius. Winkler did the same by a spark from his finger; and he succeeded in inflaming French brandy and other weaker spirits after they had been heated. Gordon kindled spirits by a jet of electrified water. Dr. Miles inflamed phosphorus by the electric spark; and oil, pitch, and sealing-wax, when strongly heated, were set on fire by similar means. We refer the student for lists of the works of the philosophers just mentioned, to the admirable bibliography given by Young, *Natural Philosophy*, p. 515.

Leyden phial, 1745.

These striking effects were all produced by the electricity obtained immediately from an excited electric; but a great step was now made in the science, by the discovery of a method of accumulating and preserving electricity in large quantities. The author of this great invention is not distinctly known; but there is reason to believe that a monk of the name of Kleist, a person of the name of Cuneus, and Professor Muschenbroeck of Leyden had each the merit of an independent inventor. The invention by which this accumulation was effected, was called the *Leyden Jar* or *Phial*, because it was principally in Leyden that it was either invented or tried. Having observed that excited electrics soon lost their electricity in the open air, and that their loss was accelerated when the atmosphere was charged with moisture or other conducting materials, Muschenbroeck conceived that the electricity of bodies might be retained by surrounding them with bodies which did not conduct it. In putting this idea to the test of experiment, he electrified some water in a glass bottle, and a communication having been made between the water and the prime conductor, the assistant, who was holding the bottle, on trying to disengage the communicating wire, received a sudden shock in his arms and breast, and thus established the efficacy of the Leyden Jar.

Sir Wm. Watson (1715–1807).

Sir William Watson made some important experiments at this period of our history (Memoirs in *Phil. Trans.* about 1747). He succeeded in firing gunpowder by the electric spark; and by mixing the gunpowder with a little camphor he discharged a musket by the same power. He also fired hydrogen by the electric spark; and he kindled both spirits of wine and hydrogen by means of a drop of cold water, and even with ice. In the German experiments the fluid or solid to be inflamed was set on fire by an electrified body; but Sir William Watson placed the fluid in the hands of an electrified person, and set it on fire by causing a person not electrified to touch it with his finger. Sir William Watson first observed the flash of light which attends the discharge of the Leyden phial, and it is to him that we owe the present improved form of the Leyden phial, in which it is coated both without and within with tinfoil. Dr. Bevis indeed had suggested the outside coating, and at Smeaton's recommendation, he coated a pane of glass on both sides, and within an inch of the edge, with tinfoil; but still the idea of coating the jar doubly belongs to Sir William Watson.

Experiments of the Royal Society.

A party of the Royal Society, with the president at their head, and Sir William Watson as their chief operator, entered upon a series of magnificent experiments, for the purpose of determining the velocity of the electric fluid, and the distance to which it could be conveyed. The French savans had conveyed the influence of the Leyden jar through a circuit of 12,000 feet; and in one case the basin at the Tuileries, containing about an acre of water, formed part of the circuit; but the English philosophers made a more complete series of experiments, of which the following were the results:—

1. That in all their operations, when the wires have been properly conducted, the electrical commotions from the charged phial have been very considerable only when the observers at the extremities of the wire have touched some substance readily conducting electricity with some part of their bodies.

2. That the electrical commotion is always felt most sensibly in those parts of the bodies of the observers which are between the conducting wires and the nearest and the most non-electric substance, or, in other words, so much of their bodies as comes within the electrical circuit.

3. That on these considerations we infer that the electrical power is conducted between these observers by any non-electric substances which happen to be situated between them, and contribute to form the electrical circuit.

4. That the electrical commotion has been perceptible to two or more observers at considerable distances from each other, even as far as two miles.

5. That when the observers have been shocked at the end of two miles of wire, we infer that the electrical circuit is four miles, viz., two miles of wire, and the space of two miles of the non-electric matter between the observers, whether it be water, earth, or both.

6. That the electrical commotion is equally strong, whether it is conducted by water or dry ground.

7. That if the wires between the electrifying machine and the observers are conducted on dry sticks, or other substances non-electric in a slight degree only, the effects of the electrical power are much greater than when the wires in their progress touch the ground, or moist vegetables, or other substances in a great degree non-electric.

8. That by comparing the respective velocities of electricity and sound, that of electricity, in any of the distances yet experienced, is nearly instantaneous.

In the following year these experiments were resumed with the view of ascertaining the absolute velocity of electricity at a certain distance, and it was found "that through the whole length of a wire 12,276 feet the velocity of electricity was instantaneous."

The theory of positive and negative electricity, which was afterwards elaborated by Franklin, was distinctly announced by Sir W. Watson. He lays it down as a law that in electrical operations there is an afflux of "electric fluid" to the globe and the conductor, and also an efflux of the same matter from them. In the case of two insulated persons, the one in contact with the rubber and the other with the conductor, he observed that either of them would communicate a much stronger spark to the other than to any bystander. The electricity of the one, he says, became more rare than it is naturally, and that of the other more dense, so that the density of the electricity in the two insulated persons differed more than that between either of them and a bystander.

A variety of interesting experiments were made about this time by Le Monnier, Nollet, Winckler, Ellicott, Jallabert, Boze, Menon, Smeaton, and Miles. In 1746 Le Monnier confirmed the result previously obtained by Gray, that electricity is communicated to homogeneous bodies in proportion to their surfaces only. Boze discovered that capillary tubes which discharged water by drops afforded a continuous stream when electrified. The Abbé Nollet (*Essai sur l'Electricité*, 1746; *Recherches*, 1749; *Lettres*, 1753), the friend and coadjutor of Dufay, ascertained that electricity increases the natural evaporation of fluids, and that the evaporation is hastened by placing them in non-electric vessels. Jallabert confirmed the result previously obtained by Watson, that electricity passes through the substance of a conducting wire, and not along its surface. Smeaton found that the red-hot part of an iron bar could be as strongly electrified as the cold parts on each side of it. Dr. Miles kindled common spirits by a stick of black sealing-wax excited by dry flannel. Ellicott conceived that the particles of the electric fluid repel each other, while they attract those of all other bodies. Mowbray concluded that the vegetation of two myrtles was hastened by electrifying them,—a result which Nollet confirmed in the case of vegetating seeds. The Abbé Menon found that cats, pigeons, sparrows, and chaffinches lost weight by being electrified for five or six hours, and that the same result was true of the human body; and hence it was concluded that electricity augments the insensible perspiration of animals.

Franklin (1706-90).

A high place in the history of electricity must be allotted to the name of Dr. Benjamin Franklin of Philadelphia. His researches did much to extend our theoretical and practical knowledge of electricity, and the clearness and vigor of his style made his writings popular, and spread the study of the subject.

One of the first labors of the American philosopher was to present, in a more distinct form, the theory of positive and negative electricity, which Sir W. Watson had been the first to suggest. He showed that electricity is not created by friction, but merely collected from its state of diffusion through other matter by which it is attracted. He asserted that the glass globe, when rubbed, attracted the electrical fire, and took it from the rubber, the same globe being disposed, when the friction ceases, to give out its electricity to any body which has less. In the case of the charged Leyden jar, the inner coating of tinfoil had received more than its ordinary quantity of electricity, and was therefore electrified *positively* or *plus*, while the outer coating of tinfoil having had its ordinary quantity of electricity diminished, was electrified *negatively* or *minus.* Hence the cause of the shock and spark when the jar is discharged, or when the superabundant plus electricity of the inside is transferred by a conducting body to the defective or minus electricity of the outside. This theory of the Leyden phial Franklin established in the clearest manner, by showing that the outside and the inside coatings possessed opposite electricities, and that, in charging it, exactly as much electricity is added on one side as is subtracted from the other. The abundant discharge of electricity by points was observed by Franklin in his earliest experiments, and also the power of points to conduct it copiously from an electrified body. Hence he was furnished with a simple method of collecting electricity from other bodies; and he was thus enabled to perform those remarkable experiments which we shall now proceed to explain. Hawksbee, Wall, and Nollet had successively suggested the similarity between lightning and the electric spark, and between the artificial snap and the natural thunder. Previous to the year 1750, Franklin drew up a statement, in which he showed that all the general phenomena and effects which were produced by electricity had their counterpart in lightning. After waiting some time for the erection of a spire at Philadelphia, by means of which he thought to bring down the electricity of a thunder-storm, he conceived the idea of sending up a kite among the clouds themselves. With this view, he made a small cross of two small light strips of cedar, the arms being sufficiently long to reach to the four corners of a large thin silk handkerchief when extended. The corners of the handkerchief were tied to the extremities of the cross, and when the body of the kite was thus formed, a tail, loop, and string were added to it. The body was made of silk, to enable it to bear the violence and wet of a thunder-storm. A very sharp-pointed wire was fixed at the top of the upright stick of the cross, so as to rise a foot or more above the wood. A silk ribbon was tied to the end of the twine next the hand, and a key suspended at the junction of the twine and silk. In company with his son, Franklin raised the kite like a common one, in the first thunder-storm, which happened in the month of June, 1752. To keep the silk ribbon dry, he stood within a door, taking care that the twine did not touch the frame of the door; and when the thunder-clouds came over the kite, he watched the state of the string. A cloud passed without any electrical indications, and he began to despair of success. He saw, however, the loose filaments of the twine standing out every way, and he found them to be attracted by the approach of his finger. The suspended key gave a spark on the application of his knuckle, and when the string had become wet with the rain, the electricity became abundant; a Leyden jar was charged at the key, and by the electric fire thus obtained, spirits were inflamed, and all the other electrical experiments performed which had been formerly made by excited electrics. In subsequent trials with another apparatus, he found that the clouds were sometimes positively and sometimes negatively electrified, and so demonstrated the perfect identity of lightning and electricity. Having thus succeeded in drawing the electric fire from the clouds, Franklin conceived the idea of protecting buildings from lightning, by erecting on their highest parts pointed iron wire or conductors communicating with the ground. The electricity of a hovering or a passing cloud would thus be carried off slowly and silently; and if the cloud was highly charged, the lightning would strike in preference the elevated conductors.

The most important of Franklin's electrical writings are his *Experiments and Observations on Electricity made at Philadelphia*, 1751–54; his *Letters on Electricity*, and various memoirs and letters, *Phil. Trans.*, 1756, 1760, etc.

About the same time that Franklin was making his kite experiment in America, D'Alibard and others in France had erected a long iron rod at Marli, and obtained results agreeing with those of Franklin. Similar investigations were pursued by many others, among whom Father Beccaria deserves especial mention.

Death of Richman, 1753.

These experiments were often dangerous, and in one case a fatal accident occurred. Professor Richman of St. Petersburg, had erected on his house, an iron rod to collect the electricity of thunder-clouds. On the 6th August, 1753, during a thunder-storm, he was observing, along with his friend Sokolow, the indications of an electrometer which formed part of his apparatus, when a tremendous thunder-clap burst over the neighborhood. Richman bent to observe the electrometer; while in this position, his head being a foot from the iron rod, Sokolow saw a globe of bluish fire about the size of the fist shoot from the iron rod to the professor's head, with a report like that of a pistol. The shock was fatal; Richman fell back upon a chest and instantly expired. Sokolow was stupefied and benumbed, and the red-hot fragments of a metallic wire struck his clothes, and covered them with burnt marks.

Canton (1715–72).

One of the most diligent laborers in the field of electrical science was an Englishman, John Canton (*Phil. Trans.*, 1753–54). Before his time it had been assumed as indisputable that the same kind of electricity was invariably produced by the friction of the same electric,—that glass, for example, yielded aways *vitreous*, and amber always *resinous* electricity. Having roughened a glass tube by grinding its surface with emery and sheet lead, he found that it possessed vitreous or positive electricity when excited with oiled silk, but resinous electricity when excited with new flannel. He found, in short, that vitreous or resinous electricity might, in certain cases, be developed at will in the same tube, by altering the surfaces of the tube and the exciting rubber. Removing the polish from one half of the tube, he excited the different electricities with the same rubber at a single stroke, and, curiously enough, the rubber was found to move much more easily over the rough than over the polished half. Canton likewise discovered that glass, amber, sealing-wax, and calcareous spar were all electrified positively when taken out of mercury; and hence he was led to the important practical discovery that an amalgam of mercury and tin was most efficacious in exciting glass when applied to the surface of the rubber. Canton discovered, and to a certain extent explained by the then prevalent theory of "electrical atmospheres," the fundamental fact of *electrification by induction*. He also found that the air in a room could be electrified positively or negatively, and might remain thus electrified for a considerable time.

Beccaria (1716–81).

Beccaria, a celebrated Italian physicist, kept up the spirit of electrical discovery in Italy. He showed that water is a very imperfect conductor of electricity, that its conducting power is proportional to its quantity, and that a small quantity of water opposes a powerful resistance to the passage of electricity. He succeeded in making the electric spark visible in water, by discharging shocks through wires that nearly met in tubes filled with water. In this experiment the tubes, though sometimes eight or ten lines thick, were burst in pieces. Beccaria likewise demonstrated that air adjacent to an electrified body gradually acquired the same electricity, that the electricity of the body is diminished by that of the air, and that the air parts with its electricity very slowly. He considered that there was a mutual repulsion between the particles of the electric fluid and those of air, and that in the passage of the former through the latter a temporary vacuum was formed. Beccaria's experiments on atmospherical electricity are of the greatest interest to the meteorologist. For further account of his work, see his *Lettere dell' Elettr.*, 1758; *Experimenta*, 1772; and letters, etc., in *Phil. Trans.* about 1770.

Symmer, c. 1759.

The science of electricity owes several practical as well as theoretical observations to Robert Symmer (*Phil. Trans.*, about 1759). In pulling off his stockings in the evening, he had often remarked that they not only gave a crackling noise, but even emitted sparks in the dark. The electricity was most powerful when a silk and a worsted stocking had been worn on the same leg, and it was best exhibited by putting the hand between the leg and the stockings, and pulling them off together. The one stocking being then drawn out of the other, they appeared more or less inflated, and exhibited the attractions and repulsions of electrified bodies. Two white silk stockings, or two black ones, when put on the same leg and taken off, gave no electrical indications. When a black and a white stocking were put on the same leg, and after ten minutes taken off, they were so much inflated when pulled asunder, that each showed the entire shape of the leg, and at the distance of a foot and a half they rushed to meet each other.

> "But what appears most extraordinary is, that when they are separated, and removed at a certain distance from each other, their electricity does not appear to have been in the least impaired by the shock they had in meeting. They are again inflated, again attract and repel, and are as ready to rush together as before. When this experiment is performed with two black stockings in one hand, and two white in the other, it exhibits a very curious spectacle; the repulsion of those of the same color, and the attraction of those of different colors, throws them into an agitation that is not unentertaining, and makes them catch each at that of its opposite color, at a greater distance than one would expect. When allowed to come together, they all unite in one mass. When separated, they resume their former appearance, and admit of the repetition of the experiment as often as you please, till their electricity, gradually wasting, stands in need of being recruited."

Symmer likewise found that a Leyden jar could be charged by the stockings either positively or negatively, according as the wire from the neck of the jar was presented to the black or the white stocking. When the electricity of the white stocking was thrown into the jar, and then the electricity of the black one, or *vice versâ*, the jar was not electrified at all. With the electricity of two stockings he charged the jar to such a degree that the shock from it reached both his elbows; and by means of the electricity of four silk stockings he kindled spirits of wine in a teaspoon which he held in his hand, and the shock was at the same time felt from the elbows to the breast. Symmer has the merit of having first maintained the theory of two distinct fluids, not independent of each other, as Dufay supposed them to be, but co-existent, and, by counteracting each other, producing all the phenomena of electricity. He conceived that when a body is said to be positively electrified, it is not simply that it is possessed of a larger share of electric matter than in a natural state, nor, when it is said to be negatively electrified, of a less; but that, in the former case, it is possessed of a larger portion of one kind of electricity, and in the latter, of a larger portion of the other; while a body, in its natural state, remains unelectrified, because there is an equal amount of the two everywhere within it.

Contemporary with Symmer were Delaval, Wilson, Cigna, Kinnersley, Wilcke, and Priestley (for the works of these electricians consult Young). Delaval found that the sides of vessels that were perfect conductors were non-conductors, and that animal and vegetable bodies lost their conducting power when reduced to ashes. Wilson concluded that when two electrics are rubbed together, the harder of the two is generally electrified positively and the other negatively, the electricities always being opposite. Cigna made many curious experiments by using silk ribbons in place of the silk stockings of Symmer. Kinnersley, the friend of Franklin, made some important experiments on the elongation and fusion of iron wires, when a strong charge was passed through them in a state of tension (*Phil. Trans.*, 1763); he also experimented on the disruptive discharge in air. Wilcke brought to light many phenomena respecting the electrification produced by the melting of electric substances.

Pyro-electricity of minerals.

The pyro-electricity of minerals, or the faculty possessed by some minerals of becoming electric by heat, and of exhibiting negative and positive poles, now began to attract the notice of philosophers. There is reason to believe that the *lyncurium* of the ancients, which, according to Theophrastus, attracted light bodies, was the *tourmaline*, a Ceylon mineral, in which the Dutch had early recognized the same attractive property, whence it got the name of *Aschentrikker*, or attractor of ashes. In 1717 M. Lemery exhibited to the Academy of Sciences a stone from Ceylon which attracted light bodies; and Linnæus, in mentioning the experiments of Lemery, gives the stone the name of *Lapis Electricus*. The Duke de Noya was led in 1758 to purchase some of the stones called tourmaline in Holland, and, assisted by Daubenton and Adanson, he made a series of experiments with them, a description of which was published. The subject, however, had engaged the attention of Æpinus, a celebrated German philosopher, who published an account of them in 1756. Hitherto nothing had been said respecting the necessity of heat to excite the tourmaline; but it was shown by Æpinus that a temperature between 99½° and 212° Fahr. was requisite for the development of its attractive powers. Benjamin Wilson (*Phil. Trans.*, 1763, etc.), Priestley, and Canton continued the investigation; but it was reserved for the Abbé Haüy to throw a clear light on this curious branch of the science (*Traité de Mineralogie*). He found that the electricity of the tourmaline decreased rapidly from the sum-

Æpinus (1724–1806).

mits or poles towards the middle of the crystal, where it was imperceptible; and he discovered that if a tourmaline is broken into any number of fragments, each fragment, when excited, has two opposite poles. Haüy discovered the same property in the Siberian and Brazilian topaz, borate of magnesia, mesotype, prehnite, sphene, and calamine. He also found that the polarity which minerals receive from heat has a relation to the secondary forms of their crystals,—the tourmaline, for example, having its resinous pole at the summit of the crystal which has three faces, and its vitreous pole at the summit which has six faces. In the other pyro-electrical crystals above mentioned, Haüy detected the same deviation from the rules of symmetry in their secondary crystals which occurs in tourmaline. Brard discovered that pyro-electricity was a property of the axinite; and it was afterwards detected in other minerals. In repeating and extending the experiments of Haüy, Sir David Brewster discovered that various artificial salts were pyro-electrical; and he mentions tartrate of potash and soda, and tartaric acid, as exhibiting this property in a very strong degree. He also made many experiments with the tourmaline when cut into thin slices, and reduced to the finest powder, in which state each particle preserved its pyro-electricity; and he showed that *scolezite* and *mesolite*, even when deprived of their water of crystallization and reduced to powder, preserve their property of becoming electrical by heat. When this white powder is heated and stirred about by any substance whatever, it collects in masses like new fallen snow, and adheres to the body with which it is stirred. (For Sir David Brewster's work on pyro-electricity see *Trans. R.S.E.*, 1845; *Phil. Mag.*, Dec., 1847; *Edinburgh Journal of Science*, Oct., 1824 and 1825.)

In addition to his experiments on the tourmaline, Æpinus made several on the electricity of melted sulphur; and in conjunction with Wilcke, he investigated the subject of electric atmospheres, and discovered a beautiful method of charging a plate of air by suspending large wooden boards coated with tin, and having their surfaces near each other and parallel. Æpinus, however, has been principally distinguished by his ingenious theory of electricity, which he has explained and illustrated in a separate work (*Tentamen Theoriæ Electricitatis et Magnetismi*) which appeared at St. Petersburg in 1759. This theory is founded on the following principles. 1. The particles of the electric fluid repel each other with a force decreasing as the distance increases. 2. The particles of the electric fluid attract the particles of all bodies, and are attracted by them, with a force obeying the same law. 3. The electric fluid exists in the pores of bodies; and while it moves without any obstruction in non-electrics, such as metals, water, etc., it moves with extreme difficulty in electrics, such as glass, rosin, etc. 4. Electrical phenomena are produced either by the transference of the fluid from a body containing more to one containing less of it, or from its attraction and repulsion when no transference takes place.

Electricity of fishes.

The electricity of fishes, like that of minerals, now began to excite very general attention. The ancients, as we have seen, were acquainted with the benumbing power of the torpedo, but it was not till 1676 that modern naturalists attended to this remarkable property. The Arabians had long before given this fish the name of *raad* or lightning; but Redi was the first who communicated the fact that the shock was conveyed to the fisherman by means of the line and rod, which connected him with the fish. Lorenzini published engravings of its electrical organs; Reaumur described the electrical properties of the fish; Kämpfer compared the effects which it produced to lightning; but Bancroft was the first person who distinctly suspected that the effects of the torpedo were electrical. In 1773 Walsh (*Phil. Trans.*, 1773–5) and Ingenhousz proved, by many curious experiments, that the shock of the torpedo was an electrical one; and Hunter (*Phil. Trans.*, 1773–5) examined and described the anatomical structure of its electrical organs. Humboldt (*Ann. de Chem. et de Phys.*, i. 15), Gay-Lussac, and Geoffroy pursued the subject with success; and Cavendish (*Phil. Trans.*, 1776) constructed an artificial torpedo, by which he imitated the actions of the living animal. The subject was also investigated by Todd, Sir Humphry Davy (*Phil. Trans.*, 1829), John Davy, and Faraday (*Exp. Res.*, vol. ii.). The power of giving electric shocks has been discovered also in the *Gymnotus electricus*,[1] the *Malapterurus electricus*,[2] the *Trichiurus electricus*,[3] and the *Tetraodon electricus*.[3] The most interesting and the best known of these singular fishes is the *Gymnotus* or Surinam eel. Humboldt gives a very graphic account of the combats which are carried on in South America between the gymnotī and the wild horses in the vicinity of Calabozo.

Cavendish (1731–1810).

Among the cultivators of electricity, Henry Cavendish is entitled to a distinguished place. Before he had any knowledge of the theory of Æpinus he had communicated to the Royal Society a similar theory of electrical phenomena. As, however, he had carried the theory much further, and considered it under a more accurate point of view, he did not hesitate to give his paper to the world (*Phil. Trans.*, 1771). Cavendish made some accurate experiments on the relative conducting power of different substances. He found that electricity experiences as much resistance in passing through a column of water one inch long as it does in passing through an iron wire of the same diameter 400,000,000 inches long, whence he concluded that iron wire conducts 400,000,000 times as well as rain or distilled water. He found that a solution of one part of salt in one of water conducts a hundred times better than fresh water, and that a saturated solution of sea-salt conducts seven hundred and twenty times better than fresh water. Cavendish likewise determined by nice experiments that the quantity of electricity on coated glass of a certain area increased with the thinness of the glass, and that on different coated plates the quantity was as the area of the coated surface directly, and as the thickness of the glass inversely. Although electricity had been employed as a chemical agent in the oxidation and fusion of metals, yet it is to Cavendish that we owe the first of those brilliant inquiries which have done so much for the advancement of modern chemistry. By using different proportions of oxygen and hydrogen, and examining the products which they formed after explosion with the electric spark, he obtained a proportion of which the product was pure water (*Phil. Trans.*, 1784–5). The decomposition of water by the electric spark was first effected by Paets Van Troostwijk and Deiman; improved methods of effecting it were discovered and used by Pearson, Cuthbertson, and Wollaston (*Phil. Trans.*, 1801).

Galvani (1737–98) and Volta (1745–1827).

The great discovery made by Galvani in 1790, that the contact of metals produced muscular contraction in the frog, and the invention of the voltaic pile, in 1800, by Volta led to the recognition of a new kind of electricity called *Galvanic* or *Voltaic Electricity*, which is now proved to be identical with frictional electricity. The chemical effects of the voltaic pile far transcend those of ordinary electricity. In 1800 Nicolson and Carlisle discovered the power of the pile to decompose water; and in 1807 (*Bakerian Lecture*) Sir Humphry Davy decomposed the earths and the alkalies, and thus created a new epoch in the history of chemistry.

Coulomb (1736–1806).

Contemporaneous with Cavendish was Coulomb, one of the most eminent experimental philosophers of the last century. In order to determine the law of electrical action, he invented an instrument called a *torsion balance*, which has since his time been universally used in all delicate researches, and which is particularly applicable to the measurement of electrical and magnetical actions. Æpinus and Cavendish had considered the action of electricity as diminishing with the distance; but Coulomb proved, by a series of elaborate experiments, that it varied, like gravity, in the inverse ratio of the square of the distance. Dr. Robison had previously determined, without, however, having published his experiments, that in the mutual repulsion of two similarly electrified spheres, the law was slightly in excess of the inverse duplicate ratio of the distance, while in the attraction of oppositely electrified spheres the deviation from that ratio was in defect; and hence he concluded that the law of electrical action was similar to that of gravity. Adopting the hypothesis of two fluids, Coulomb investigated experimentally and theoretically the distribution of electricity on the surface of bodies. He determined the law of its distribution between two conducting bodies in contact; he measured the density of the electricity at different points of two spheres in contact; he ascertained the distribution of electricity among several spheres (whether equal or unequal) placed in contact in a straight line; he measured the distribution of electricity on the surface of a cylinder, and its distribution between a sphere and cylinder of different lengths but of the same diameter. His experiments on the dissipation of electricity possess also a high value. He found that the momentary dissipation was proportional to the degree of electrification at the time, and that, when the charge was moderate, its dissipation was not altered in bodies of different kinds or shapes. The temperature and pressure of the atmosphere did not produce any sensible change; but he concluded that the dissipation was nearly proportional to the cube of the quantity of moisture in the air. In examining the dissipation which takes place along imperfectly insulating substances, he found that a thread of gum-lac was the most perfect of all insulators; that it insulated ten times as well as a dry silk thread; and that a silk thread covered with fine sealing-wax insulated as powerfully as gum-lac when it had four times its length. He found also that the dissipation of electricity along insulators was chiefly owing to adhering moisture, but in some measure also to a slight conducting power. For the memoirs of Coulomb see *Mém. de Math. et Phys. de l'Acad. de Sc.*, 1785, etc.

[3] Weak.

Laplace, Lavoisier, and Volta.

Towards the end of the last century a series of experiments was made by Laplace, Lavoisier, and Volta (*Phil. Trans.*, 1782, or *Collezione dell' Op.*), from which it appeared that electricity is developed when solid or fluid bodies pass into the gaseous state. The bodies which were to be evaporated or dissolved were placed upon an insulating stand, and made to communicate by a chain or wire with a Cavallo's electrometer, or with Volta's condenser, when it was suspected that the electricity increased gradually. When sulphuric acid diluted with three parts of water was poured upon iron filings, hydrogen was disengaged with a brisk effervescence; and at the end of a few minutes the condenser was so highly charged as to yield a strong spark of negative electricity. Similar results were obtained when charcoal was burnt on a chafing dish. Volta, who happened to be at Paris when these experiments were made, and who took an active part in them, subsequently observed that the electricity produced by evaporation was always negative. He found that burning charcoal gives out negative electricity; and in other kinds of combustion he obtained distinct electrical indications. In this state of the subject Saussure (*Voyage dans les Alpes*, t. ii. p. 808, *et seqq.*) undertook a series of elaborate experiments on the electricity of evaporation and combustion. In his first trials he found that the electricity was sometimes positive and sometimes negative when water was evaporated from a heated crucible of iron; but he afterwards found it to be always positive both in an iron and a copper crucible. In a silver and a porcelain crucible the electricity was negative. The evaporation of alcohol and of ether in a silver crucible also gave negative electricity. Saussure made many fruitless trials to obtain electricity from combustion, and he likewise failed in his attempt to procure it from evaporation without ebullition. Many valuable additions were about this time made to electrical apparatus, as well as to the science itself, by Van Marum, Cavallo, Nicholson, Cuthbertson, Brooke, Bennet, Read, Morgan, Henley, and Lane; but these cannot here be noticed in detail.

Saussure.

Application of analysis to electricity.

The application of analysis to electrical phenomena may be dated from the commencement of the present century. Coulomb had considered only the distribution of electricity on the surface of spheres; but Laplace undertook to investigate its distribution on the surface of ellipsoids of revolution, and he showed that the thickness of the coating of fluid at the pole was to its thickness at the equator as the polar is to the equatorial diameter. Biot (*Traité de Physique Exp. et Math.*) has extended this investigation to all spheroids differing little from a sphere, whatever may be the irregularity of their figure. He likewise determined analytically that the losses of electricity form a geometrical progression when the two surfaces of a jar or plate of coated glass are discharged by successive contacts; and he found that the same law regulates the discharge when a series of jars or plates are placed in communication with each other.

Biot.

Poisson.

It is to Poisson (*Mém. de l'Inst. Math. et Phys.*, 12, 1811, etc.), however, that we are mainly indebted for having brought the phenomena of electricity under the dominion of analysis, and placed it on the same level as the more exact sciences. Assuming the hypothesis of two fluids, he deduced theorems for determining the distribution of the electric fluid on the surface of two conducting spheres when they are either placed in contact or at any given distance. The truth of these theorems had been established by experiments performed by Coulomb long before the theorems themselves had been investigated.

Magnetic action of electric current discovered by Oersted.

Voltaic electricity had now absorbed the attention of experimental philosophers. The splendor of its phenomena, as well as its association with chemical discovery, contributed to give it popularity and importance; but the discoveries of Galvani and Volta were destined, in their turn, to pass into the shade, and the intellectual enterprise of the natural philosophers of Europe was directed to new branches of electrical and magnetical science. Guided by theoretical anticipations, Professor H. C. Oersted of Copenhagen (*Experimenta circa effectum conflictus electrici in acum magneticam*) in 1820 discovered that the electrical current of a galvanic battery, when made to pass through a platinum wire, acted upon a compass needle placed below the wire. He found that a magnetic needle placed in the neighborhood of an electric current always places itself perpendicular to the plane through the current and the centre of the needle; or, more definitely, that a magnetic north pole, carried at a constant distance round the current in the direction of rotation of an ordinary corkscrew advancing in the positive direction of the current, would always tend to move in the direction in which it is being carried.

Electrodynamics. Ampère's theory.

Scarcely had the news of Oersted's discovery reached France when a French philosopher, Ampère, set to work to develop the important consequences which it involved. Physicists had long been looking for the connection between magnetism and electricity, and had, perhaps, inclined to the view that electricity was somehow to be explained as a magnetic phenomenon. It was, in fact, under the influence of such ideas that Oersted was led to his discovery. Ampère showed that the explanation was to be found in an opposite direction. He discovered the pondero-motive action of one electric current on another, and by a series of well-chosen experiments he established the elementary laws of electrodynamical action, starting from which, by a brilliant train of mathematical analysis, he not only evolved the complete explanation of all the electro-magnetic phenomena observed before him, but predicted many hitherto unknown. The results of his researches may be summarized in the statement that an electric current in a linear circuit of any form is equivalent in its action, whether on magnets or other circuits, to a magnetic shell bounded by the circuit, whose strength at every point is constant and proportional to the strength of the current. By his beautiful theory of molecular currents, he gave a theoretical explanation of that connection between electricity and magnetism which had been the dream of previous investigators. If we except the discovery of the laws of the induction of electric currents made about ten years later by Faraday, no advance in the science of electricity can compare for completeness and brilliancy with the work of Ampère. Our admiration is equally great whether we contemplate the clearness and power of his mathematical investigations, the aptness and skill of his experiments, or the wonderful rapidity with which he elaborated his discovery when he had once found the clew.

Recent progress of electro-dynamics.

In 1821 Faraday, who was destined a little later to do so much for the science of electricity, discovered electro-magnetic rotation (*Quarterly Journal*, xii.), having succeeded in causing a horizontal wire carrying a current to rotate continuously across the vertical lines of a field of magnetic force. The experiment was very soon repeated in a variety of forms by De la Rive, Barlow, Ritchie, Sturgeon, and others; and Davy (*Phil. Trans.*), in 1823, observed that, when two wires connected with the pole of a battery were dipped into a cup of mercury placed on the pole of a powerful magnet, the fluid metal rotated in opposite directions about the two electrodes. The rotation of a magnet about a fixed current and about its own axis was at once looked for, and observed by Faraday and others. The deflection of the voltaic arc by the magnet had been observed by Davy in 1821 (*Phil. Trans.*); and in 1840 Walker observed the rotation of the luminous discharge in a vacuum tube. For many beautiful experiments on the influence of the magnet on the strata, etc., in vacuum tubes, we are indebted to Plücker, De la Rive, Grove, Gassiot, and others who followed them.

Electro-magnetic engines. One of the first machines in which a continuous motion was produced by means of the repulsions and attractions between electro-magnets and fixed magnets or electro-magnets was invented by Ritchie (*Phil. Trans.*, 1833). The artifice in such machines consists in reversing the polarity of one of the electro-magnets when the machine is near the position of equilibrium. For a general theory of these machines, showing the reasons why they are not useful as economic motive powers, see Jacobi (*Mémoire sur l'Application de Électro-magnétisme au Mouvement des Machines*, Potsdam, 1835), and Joule (*Mech. Mag.*, xxxvi.). Electro-magnetic engines have, however, found a restricted use in scientific workshops, such as Froment's, in driving telegraphic apparatus, etc.

Magnetization by electric current. In 1820 Arago (*Ann. de Chim. et de Phys.*, t. xv.) and Davy (*Annals of Philosophy*, 1821) discovered independently the power of the electric current to magnetize iron and steel. Savary (*Ann. de Chim. et de Phys.*, t. xxxiv., 1827) made some very curious experiments on the alternate directions of magnetization of needles placed at different distances from a wire conveying the discharge of a Leyden jar. The dependence of the intensity of magnetization on the strength of the current was investigated by Lenz and Jacobi (*Pogg. Ann.*, xlvii., 1839), and Joule found that magnetization did not increase proportionately with the current, but reached a maximum (Sturgeon's *Ann. of El.* iv. 1839). The farther development of this subject, which really belongs to magnetism, has been carried on by Weber, Müller, Von Waltenhofen, Dub, Wiedemann, Quintus Icilius, Riecke, Stoletow, Rowland, and others. The use of a core of soft iron, magnetized by a helix surrounding it, has become universal in all kinds of electrical apparatus. Electro-magnets of great power have in this way been constructed and used in electrical researches by Brewster, Sturgeon, Henry, Faraday, and others.

Recent progress of electro-dynamics. The most illustrious among the successors of Ampère was Wilhelm Weber. He greatly improved the construction of the galvanometer, and invented the electro-dynamometer. To these instruments he applied the mirror scale and telescope method of reading, which had been suggested by Poggendorff, and used by himself and Gauss in magnetic measurements about 1833. In 1846 he proceeded with his improved apparatus to test the fundamental laws of Ampère. The result of his researches was to establish the truth of Ampère's principles, as far as experiments with closed circuits could do so, with a degree of accuracy far beyond anything attainable with the simple apparatus of the original discoverer. The experiments of Weber must be looked upon as the true experimental evidence for the theory of Ampère, and as such they form one of the cornerstones of electrical science.

Theory of electro-dynamics. While experiment was thus busy, theory was not idle. In 1845 Grassman published (*Pogg. Ann.*, lxiv.) his *Neue Theorie der Electrodynamik*, in which he gives an elementary law different from that of Ampère, but leading to the same results for closed circuits. In the same year F. E. Neumann published yet another law. In 1846 Weber announced his famous hypothesis connecting electro-statical and electro-dynamical phenomena. Much has been written on the subject by Carl Neumann, Riemann, Stefan, Clausius, and others. Very important are three memoirs by Helmholtz, in *Crelle's Journal* (1870–2–4), in which a general view is taken of the whole question, and the works of his predecessors are critically handled. We shall have occasion, in the body of the article, to refer to the dynamical theory of Clerk Maxwell, which promises to effect a revolution in this part of electrical science.

Thermo-electricity. By his discovery of thermo-electricity in 1822 (*Pogg. Ann.*, vi.), Seebeck opened up a new department. He found that when two different metals are joined in circuit there will be an electric current in the circuit if the junctions are not at the same temperature; he arranged the metals in a thermo-electric series, just as Volta and his followers had arranged them in a contact series. Cumming (*Annals of Phil.*, 1823) found that the order of the metals was not the same at different temperatures. This phenomenon has been called thermo-electric inversion. In 1834 Peltier discovered that if a current be sent round a circuit of two metals in the direction in which the thermo-electro-motive force would naturally send it, then the hot junction is cooled, and the cool junction heated. This effect, which is reversible, and varies as the strength of the current, is called the Peltier effect. Sir W. Thomson made many experiments on thermo-electricity, and applied to the experimental results the laws of the dynamical theory of heat. His reasonings led him to predict a new thermo-electric phenomenon, the actual existence of which he afterwards verified by an elaborate series of very beautiful experiments (*Phil. Trans.*, 1856). He has given a general theory of the thermo-electric properties of matter, taking into account the effect of structure, etc. His experimental researches have been ably continued by Professor Tait, who, guided by theoretical considerations to the conjecture that the curves in what Thomson called the "thermo-electric diagram"[1] must be straight lines, made an extended series of experiments, and showed that they were in general very approximately either straight lines or made up of pieces of straight lines. Our knowledge of thermo-electricity has been advanced by Becquerel, Magnus, Matthiessen, Leroux, Avenarius, and others. Thermo-electric batteries of considerable power have been constructed by Markus, Noë, and Clamond, and employed more or less in the arts.

Magnetism of rotation. In 1824 Arago (*Ann. de Chim. et de Phys.*, t. xxvii. etc.) made a remarkable discovery, which led ultimately to results of the greatest importance. He found that when a magnetic needle is suspended over a rotating copper disc the needle tends to follow the motion of the disc. This phenomenon, which has been called the "magnetism of rotation," excited great interest; Barlow (*Phil. Trans.*, 1825), Herschel, Seebeck (*Pogg. Ann.*, vii., 1826), and Babbage (*Phil. Trans.*, 1825) made elaborate researches on the subject; and Poisson (*Mém. de l'Acad.*, vii., 1826) attempted to give a theoretical explanation in his memoir on magnetism in motion. The true explanation was not arrived at until Faraday took up the subject a little later. We may mention here, however, the experiments of Plücker, Matteucci, and Foucault on the damping of the motions of masses of metal between the poles of electro-magnets. The damping of a compass needle suspended over a copper plate, observed by Seebeck (*l. c.*), has been taken advantage of in the construction of galvanometers.

Induction of electric currents (Faraday). In 1831 Faraday began, with the discovery of the induction of electric currents, that brilliant series of experimental researches which has rendered his name immortal. The first experiment which he describes was made with two helices of copper wire wound side by side on a block of wood, and insulated from each other by intervening layers of twine. One of these helices was connected with a galvanometer, and the other with a battery of a hundred plates, and it was found that on making and breaking the battery circuit a slight sudden current passed through the galvanometer in opposite directions in the two cases. He also discovered that the mere approach or removal of a circuit carrying a current would induce a current in a neighboring closed circuit, and that the motion of magnets produces similar effects. To express in a concise manner his discoveries, Faraday invented his famous conception of the lines of magnetic force, or lines the direction of which at any point of their course coincides with that of the magnetic force at that point. His discovery can be thus stated:—Whenever the number of lines of force passing through a closed circuit is altered, there is an electro-motive force tending to drive a current through the circuit, whose direction is such that it would itself produce lines of force passing through the circuit in the opposite direction. Nothing in the whole history of science is more remarkable than the unerring sagacity which enabled Faraday to disentangle, by purely experimental means, the laws of such a complicated phenomenon as the induction of electric currents. The wonder is only increased when we look to his papers, and find the first dated November, 1831,[2] and another January, 1832, in which he shows that he is in complete possession of all the general principles that are yet known on the subject. Faraday very soon was able to show that the current developed by induction had all the properties of the voltaic current, and he made an elaborate comparison of all the different kinds of electricity known,—statical, dynamical, or voltaic, magneto-, thermo-, and animal electricity,—showing that

[1] A mode of representing the phenomena of thermo-electricity which has been greatly developed and improved by Tait.

[2] The first experiment seems to have been actually made on the 29th August, 1831. See Bence Jones's *Life of Faraday*, vol. ii. p. 1.

Law of Lenz.

Mathematical theory.

they were identical so far as experiment could show. In 1833, Lenz made a series of important researches (*Pogg. Ann.*, xxxi., 1834, xxxiv., 1835) which, among other results, led him to his celebrated law by means of which the direction of the induced current can be predicted from the theory of Ampère, the rule being that the direction of the induced current is always such that its electro-magnetic action tends to oppose the motion which produces it. This law leads to the same results as the principles of Faraday. The researches of Ritchie and Henry about this time, and of Dove a little later, are also of importance. In 1845, F. E. Neumann did for magneto-electric induction what Ampère did for electro-dynamics, by developing from the experimental laws of Lenz the mathematical theory of the subject (*Abh. der Berl. Akad. der Wissenschaft*, 1845–7). He discovered a function which has been called the "potential" (of one linear current on another or on itself), from which he deduced a theory of induction completely in accordance with experiment. About the same time Weber deduced the mathematical laws of induction, from his elementary law of electrical action, which, as we have already seen, he applied to explain electro-static and electro-magnetic action. In 1846 Weber, applying his improved instruments, arrived at accurate verifications of the laws of induction, which by this time had been developed mathematically by Neumann and himself. In 1849 Kirchhoff determined experimentally in a certain case the absolute value of the current induced by one circuit in another; and in the same year Edlund made a series of careful experiments on the currents of self and mutual induction, which led to the firmer establishment of the received theories. Helmholtz gave the mathematical theory of the course of induced currents in various cases, and made a series of valuable experiments in verification of his theory (*Pogg. Ann.*, lxxxiii., 1851). Worthy of mention here are also the experiments and reasonings of Felici in 1852. In the *Philosophical Magazine* for 1855, Sir W. Thomson investigated mathematically the discharge of a Leyden jar through a linear conductor, and predicted that under certain circumstances the discharge would consist of a series of decaying oscillations. This oscillatory discharge was observed in 1857 by Feddersen (*Pogg. Ann.*, cviii.). The law of Weber has been applied by Kirchhoff to the case of conductors in three dimensions. The most important of all the recent contributions to this part of electrical science is the theory of Clerk Maxwell, which aims at deducing the phenomena of the electro-magnetic field from purely dynamical principles with the aid of the fewest possible hypotheses (*Phil. Trans.*, 1864; *Electricity and Magnetism*, 1873). He has established the general equations which determine the state of the electric field, and he has by means of these equations constructed an electro-magnetic theory of light, which is full of suggestions for the philosopher, whether speculative or experimental. The theory of Helmholtz, and his valuable criticisms on the works of those that have labored in this department, are to be found in three memoirs already alluded to.

Magneto-electric machines.

Magneto-electricity has been largely applied in the arts. One of the first machines for producing electricity by induction was made by Pixii. It consisted of a fixed horse-shoe armature wound with copper wire, in front of which revolved about a vertical axis a horse-shoe magnet. The machine was furnished with a commutator for delivering the alternating currents in a common direction. By means of this machine Faraday and Hachette decomposed water and collected the disengaged gases separately. Many variations of this type of machine were constructed by Ritchie, Saxton, Clark, Von Ettingshausen, Stöhrer, Dove, Wheatstone, and others. In 1857 Siemens effected a great improvement by inventing the form of armature which bears his name. The next improvement was to replace the fixed magnets by electro-magnets, the current for which was furnished by a small auxiliary machine. Wilde's machine (1867) is of this kind. Siemens, Wheatstone, and others suggested that the fixed electro-magnet should be fed by a coil placed on the armature itself, so that starting from the residual magnetism of the armature the machine goes on increasing its action up to a certain point. Ladd's machine (1867) is constructed on this principle. The most recent of these machines is that of Gramme, the peculiarity of which is that the coil of the armature is divided up into a series of coils arranged round an axis, the object being to produce a continuous instead of a fluctuating current. It has been proposed of late to employ electro-magnetic machines in lighting streets and workshops, and the experiment has been tried with some success. They have been employed for some time back in lighthouse work. The most important inductive apparatus for the physicist is the induction coil or inductorium, which has been brought to great perfection in the workshop of Ruhmkorff. Poggendorff (*Annalen*, 1855) suggested several improvements in this kind of apparatus. Fizeau, who added the condenser (1853,) Foucault, who designed the interrupter which bears his name (1855,) and Ritchie, who devised the plan of dividing the coil into sections by insulating partitions, have all aided in bringing the instrument to perfection. Very powerful machines of this kind have been constructed. A large one in the Polytechnic Institution, London, gives a 29-inch spark, and one recently constructed by Apps, for Mr. Spottiswoode, gives a spark of 42 inches. The mathematical theory of magneto-electric machines has been treated by Maxwell (*Proc. Roy. Soc.* 1867). He has also given a theory of the action of the condenser in the inductorium (*Phil. Mag.*, 1868). Two papers by Strutt (now Lord Rayleigh) in *Phil. Mag.*, 1869–70, are very interesting in connection with the same subject.

Ohm's law.

Electro-motive force, resistance, and current strength.

In the year 1827 Dr. G. S. Ohm rendered a great service to the science of electricity by publishing his mathematical theory of the galvanic circuit (*Die Galvanische Kette mathematisch bearbeitet*). Before his time the quantitative circumstances of the electric current had been indicated in a very vague way by the use of the terms "intensity" and "quantity," to which no accurately defined meaning was attached. Ohm's service consisted in introducing and defining the accurate notions—electro-motive force, current strength, and resistance. He indicated the connection of these with experiment, and stated his famous law that the electro-motive force divided by the resistance is equal to the strength of the current. The theory on which Ohm based his law may be and has been disputed, but the law itself and the applications which Ohm and others have made of it are in the fullest agreement with all known facts. The merit of Ohm really consists in having satisfactorily analyzed a great group of phenomena which had up to his time baffled all those who attempted the task. How great his service was is easily seen when we remark the progress of those who adopted his ideas as compared with those who for a time hesitated to do so. Ohm was guided in his mathematical work by analogy with the problem of the flux of heat, and introduced for the first time into the theory of the pile the equivalent of the modern word *potential*. Ohm's word was *electroscopic force* or *tension* (*Spannung*), and he showed that the fall of the potential is uniform along a homogeneous linear conductor. He considered that the potential was analogous to the temperature, and the flow of electricity to the flow of heat, so that the former just as much as the latter obeys the law of continuity. Ohm verified his theoretical conclusions with thermo-electric piles, and he observed, as Erman (*Gilb. Ann.*, 1801) had done before him, the differences of potential at different points of the circuit. Davy, Pouillet, and Becquerel labored at the experimental verification of Ohm's law, and a great body of evidence was given by Fechner in his *Maasbestimmungen über die Galvanische Kette* (1831). The law of the fall of potential was verified by the elder Kohlrausch, who employed in his researches Volta's condenser and Dellmann's electrometer (*Pogg. Ann.*, lxxv., 1848). Later researches of a similar nature were made by Gaugain and Branly. Among recent investigations bearing on Ohm's law, the most remarkable is the verification for electrolytes by Kohlrausch (the younger) and Nippoldt. They principally used alternating currents in their researches, which were furnished by a "sine inductor," the measuring instrument employed being the electro-dynamometer of Weber. In the report of the British Association for 1876 an account is given of some experiments,[1] in which the testing of this law seems to have been carried to the limit of experimental resources. It must now be allowed to rank with the law of gravitation and the elementary laws of statical electricity as a *law of nature* in the strictest sense. Many remarkable applications of Ohm's law have been made of late, in particular to linear conductors by Ohm, Poggendorff, and especially Kirchhoff (*Pogg. Ann.*, 1845–7–8). The works of Helmholtz, Smaasen, and Kirchhoff on conduction in three dimensions must also be mentioned. Very important, on account of the experimental results with which they deal, are the calculations of Du Bois Reymond (*Pogg.*, lxxi., 1845) and Riemann (*Werke*, Leipsic, 1876) on Nobili's rings, and of Kirchhoff (*Pogg.*, lxvii., 1848), W. R. Smith (*Proc. Roy. Soc. Edin.*, 1869–70), Quincke, Stefan, Adams, and others on conduction in plates. Theoretical applications to the varying currents in submarine cables of great interest have been made by Thomson (*Phil. Mag.*, 1856) and Kirchhoff (*Pogg. Ann.*, 1857), while practical researches of the greatest importance to telegraphy have been made on this and kindred subjects by Faraday, Wheatstone, Guillemin, Varley, Jenkin, and others.

---

[1] Suggested mainly by Prof. Clerk Maxwell, and carried out by the present writer.

Measurement of current. Galvanometers.

Great improvements in galvanometers and galvanometry have been made in our time. One of the first to use an electro-magnetic instrument for measuring or indicating currents was Schweigger, who in 1820 invented the "multiplier." Nobili used (1825) the astatic "multiplier" with two needles, which is sometimes named after him. Becquerel (1837) used the electro-magnetic balance, which was employed in an improved form by Lenz and Jacobi. Pouillet invented the sine and tangent compasses (1837). The defects of the latter instrument were pointed out by Poggendorff, and remedies suggested by him as well as Wheatstone and others. Weber effected great improvements in the construction and use of galvanometers, adapted them for the measurement of transient currents, and elaborated the method of oscillations which had been much used by Fechner. In 1849 Helmholtz invented the tangent compass with two coils which bears his name. Great improvements in delicacy and promptness of action have been made by Sir William Thomson in galvanometers destined for the measurement of resistance, and for indicating the feeble currents of submarine cables.

Resistance measurement.

The measurement of resistance has been carried to great perfection, chiefly owing to the labors of those who have busied themselves in perfecting the electric telegraph. Among such the highest place must be assigned to Sir Charles Wheatstone; his memoirs in the *Philosophical Transactions* (1843) gave a great impulse to this department of our science. He invented the rheostat, which underwent several modifications, but is now superseded by the resistance box, which was first used by Siemens. The earlier methods of Ohm, Wheatstone, and others for measuring resistance were defective, because they depended on the constancy of the battery which furnished the current. These defects are completely obviated in the more modern "null methods," which may be divided into two classes—those which depend on the use of the differential galvanometer introduced by Becquerel, and those which are modifications of the Wheatstone's bridge method, invented by Christie and brought into use by Wheatstone. As examples of the latter, we may mention the methods of Thomson, and of Matthiessen and Hockin, for measuring small resistances, and Thomson's method for measuring the resistance of the galvanometer (see Maxwell's *Electricity and Magnetism*, pp. 404, 410). Many determinations of the specific resistances of metals and alloys have been made by Davy, Ohm, Becquerel, Matthiessen, and others. To Matthiessen in particular science is indebted for great improvements in method and a large body of valuable results in this department. The metals have been arranged in a series according to their conducting powers; and this series is found to be nearly the same for electricity as for heat. The conductivity of metals decreases as the temperature increases, the rate of decrease being nearly the same for most pure metals, but much smaller and more variable for alloys, which, on the other hand, have in general a large specific resistance. The earlier attempts to measure the resistance of electrolytes were not satisfactory, owing to insufficient allowance for polarization. In later times this difficulty has been overcome or avoided, and concordant results have been obtained by Beetz, Paalzow, Kohlrausch, Nippoldt, and Grotrian. The last three, using the electro-dynamometer and sine inductor, have made elaborate researches, establishing among many other interesting results that the conductivity of electrolytes increases with the temperature (*Pogg. Ann.*, 1869–74).

Electro-motive force and internal resistance.

The measurement of the electro-motive force and that of internal resistance of batteries in action are problems which, in their most general form, are inextricably connected. It is easy to measure with considerable accuracy the electro-motive force of an open battery. We have merely to connect its poles with a Thomson's electrometer, and compare the deflection thus obtained with that due to some standard electro-motive force. Another very satisfactory method is Latimer Clarke's modification of Poggendorff's compensation method (see Maxwell, 413). It is likewise not difficult to measure by a variety of methods, the most satisfactory being that of Mance (Maxwell, 411), the internal resistance of a battery when it is only traversed by a feeble current. But the measurement of the electro-motive force and internal resistance of a battery working a strong current has hardly as yet been achieved with success; not that we undervalue the ingenious and important methods of Paalzow, Von Waltenhofen, Beetz (Wiedemann, i. § 181), and Siemens (*Pogg. Ann.*, 1874). The concordant results of the last two are indeed very remarkable. Still all these methods are more or less affected by the fact that the electro-motive force of a battery depends on the current which it is sending (see Beetz in *Pogg. Ann.*, cxlii.).

Batteries.

The "crown of cups" of Volta was the parent of a great many other arrangements for the production of voltaic electricity. These had for their end either compactness or diminution of the internal resistance by enlarging the plates; we may mention the batteries of Cruickshank (1801), Wollaston (1815), and Hare (1822). In 1830 Sturgeon introduced the capital improvement of amalgamating the zinc plates. In 1840 Smee used platinum or silver plates instead of copper; by platinizing these he avoided to a considerable extent polarization by adhering hydrogen. In 1836 Daniell invented the two-fluid battery which bears his name. This battery is the best *constant* battery hitherto invented, and is, under various modifications, largely used in practical and scientific work. In the same year Grove invented his well-known battery, which surpasses Daniell's in smallness of internal resistance and in electro-motive force, although, on the other hand, it is more troublesome to manage and is unsuited for long-continued action. Cooper, in 1840, replaced the expensive platinum plates of Grove's battery by carbon. This modification was introduced in a practical form into the battery of Bunsen (1842), which is much used on the Continent, and combines to a certain extent the advantages of Grove and Daniell. Among the more recent of one-fluid batteries may be mentioned the bichromate battery of Bunsen and the Léelanché cell. It is impossible here even to allude to all the forms of battery that have been invented. We may, however, in passing notice the gravitation batteries of Meidinger and Varley, and the large tray cell of Sir William Thomson.

Electrolysis.

Following up the discoveries of Nicholson, Carlisle, Davy, and others, Faraday took up the investigation of the chemical decompositions effected by the electric current. In 1833 he announced his great law of electro-chemical equivalents, which made an epoch in the history of this part of electricity. He recognized and for the first time thoroughly explained the secondary actions which had hitherto masked the essential features of the phenomenon. Faraday's discovery gave a new measure of the current, and he invented an instrument called the voltameter, which was much used by those who followed out his discoveries. Space fails us to notice in detail the labors of those who verified and developed Faraday's discovery. De la Rive, Becquerel, Soret, Buff, Beetz, Hittorf, Matteucci, Daniell, Miller, and many others have worked in this field.

Theories of electrolysis.

Many theories of electrolysis have been given. That of Grotthuss (1805) has been held under various modifications by many physicists; but none of these theories have done more than give us a convenient mode of representing experimental results. Clausius (*Pogg. Ann.*, ci., 1857) has published a remarkable molecular theory of electrolysis, which is free from some of the objections to the views of Grotthuss and his followers.

Polarization.

The advances made in the experimental study of electrolysis reacted on the theory of the galvanic battery. It was now recognized that the cause of the inconstancy of batteries is the opposing electromotive force due to the existence of the products of decomposition at the plates of the battery. Gautherot, in 1802, observed the polarization current from electrodes which had been used for electrolysis. Ritter confirmed his discovery, and constructed on the new principle his secondary pile. Ohm also experimented on this subject. Fechner and Poggendorff suspected the existence of a transition resistance (*Uebergangswiderstand*) at the places where the chemical products were evolved. But the experiments of Lenz, Beetz, and others soon showed that a *vera causâ* existed in the electro-motive force of polarization amply sufficient to explain their results. The influence of the strength of the current, the size and nature of the plates, time, etc., on polarization have been investigated by many physicists, among whom are prominent Beetz and Poggendorff. Determinations of the electro-motive force of polarization have been made by Daniell, Wheatstone, Poggendorff, and Beetz, and recently by Tait and others. Among recent labors on polarization are to be mentioned those of Helmholtz and his pupils. We must not omit to notice here the gas battery of Grove, and the powerful secondary piles which have recently been constructed by Planté. We refer those interested in these and kindred subjects to the exhaustive accounts in Wiedemann's *Galvanismus*. Justice to all contributors to our knowledge is impossible in our limited space.

Contact and chemical theories of the pile.

This is perhaps the place to mention the great battle that raged so long between the upholders of the two rival theories of the action of the pile. Volta and his immediate successors held that the current was due to the electro-motive force of contact between the dissimilar metals in the circuit, the function of the electrolyte being simply to transmit the electricity, there being no contact force between metals and liquids. The upholders of the chemical theory sought for the origin of the current in the chemical affinity between the zinc and the acid or their equivalents in the battery, and, in the first instance at least, denied the existence of the contact force of Volta. It was soon shown, however, on the one hand, that there *was* a contact force between metals and liquids, and, on the other, that an electric current could be generated without a heterogeneous metallic circuit at all.

Later holders of both theories modified their views as experiment established the necessity for so doing. Ohm and Fechner and other Continental philosophers inclined to a modified contact theory, and Sir William Thomson at present lends his weighty authority to that side. On the other side are the great names of Faraday, Becquerel, and De la Rive. The contact theorists devoted their attention more to the electro-static phenomena of the pile, while the chemical theorists studied with great minuteness the phenomena of electrolysis, so that both theories have rendered good service to science. Now-a-days most physicists probably recognize too well the defects of both theories to think it worth while to attack either, and take refuge more or less in eclecticism.

Application of the principle of the conservation of energy.

There was one point which the older adherents of the contact theory overlooked, the importance of which was more or less dimly perceived by their chemical opponents. This was, in modern language, the question, where does the energy come from which appears as kinetic energy in the moving parts of electro-magnetic engines, as heat in the conducting wires through which a current is being driven, and so forth? It was not until the dynamical theory of heat had been perfected that the first answer to this question was given.

Joule's law.

Joule (*Phil. Mag.*, 1841) had arrived experimentally at the law which regulates the generation of heat in conductors by the electric current, and his law was verified by Lenz and Becquerel, both for metals and electrolytes. Reasoning from Joule's law on the case where the whole of the energy appears in the form of heat, Thomson (*Phil. Mag.*, 1851) established the important theorem that the electro-motive force of an electro-chemical apparatus is, in absolute measure, equal to the mechanical equivalent of the chemical action on one electro-chemical equivalent of the substance. Calculations of the electromotive force of a Daniell's cell, from the results of Joule, Andrews, and Favre and Silberman, have given numbers agreeing with the direct measurements of Bosscha. The total amount of the electro-motive force in the circuit having been thus satisfactorily determined, the question between the rival theories is reduced to the determination of the seat of this force—At which of the junctions does it act?

Electrostatics.

Besides his great services in other branches of electricity, Faraday did much to advance electrostatics. His experimental investigations on electro-static induction are of great interest, and his discovery of the effect of the medium between the electrified bodies opened out a new aspect of the phenomenon quite unsuspected by those who held too closely to the theories of action at a distance. He introduced the term specific inductive capacity, and measured the capacity of several solid substances, showing that in these it was much greater than that of air. He conceived that his results were at variance with any theory of action at a distance, and gave a theory of his own, which accounted for all his facts, and which guided him in his investigations. Matteucci and Siemens adopted the views of Faraday, and the latter introduced refined methods for measuring specific inductive capacities. Such measurements have been made in later times by Barclay and Gibson for paraffin, and by Silow for certain fluids. The most remarkable results thus obtained, however, are those of Boltzmann, who succeeded not only in detecting but in actually measuring the differences between the specific inductive capacities of different gases. Faraday had looked in vain for such differences, and concluded that the specific inductive capacity was the same for all gases. The phenomenon of the residual discharge was recognized and experimented on by Faraday. Kohlrausch, Gaugain, Wüllner, and others have also experimented on it; and quite recently Mr. Hopkinson has obtained some very interesting results regarding the superposition of residual discharges. These results are analogous to the curious phenomena of "elastic recovery" observed by Kohlrausch.

Sir W. Snow Harris was a very able experimenter, and did much to improve electro-statical apparatus. He used the electrical balance and the bifilar suspension balance invented by himself. On the strength of his results he questioned the soundness of the views of Coulomb. The work of Harris on the influence of the surrounding medium on the electric spark is of great importance. Faraday made a series of beautiful experiments on this subject, and arrived at a body of results which still form a good portion of the *established* facts on this subject. Very important in this connection are the measurements of Sir W. Thomson of the electro-motive force required to produce a spark in air between two conductors, which he has found to be disproportionally smaller for large distances than for small.

The luminous phenomena attending the electric discharge, especially in vacuum tubes such as those of Geissler, are exceedingly beautiful, and have of late formed a favorite subject of experimental study. Many interesting results have been obtained, the significance of which we may not yet rightly comprehend. Among the older labors in this field we may mention those of Plücker and Hittorf, De la Rive, Riess, Gassiot, and Varley. But even as we write our knowledge of the subject is extending, and we refrain from referring to more modern results; for historical sketching—a difficult task in any case—is unsafe in an open field like this, where some apparently insignificant fact may contain the germ of a great discovery. We may here mention the experiments of Wheatstone on the velocity of electricity, valuable less for the results he obtained than for the ingenious application of the rotating mirror, then used for the first time, which has since been applied with much success in the study of the electric discharge.

One of the greatest names in electrical science is that of Riess. In his classical research on the heating of wires by the discharge from a battery of Leyden jars, he did for electricity of high potential what Joule did for the voltaic current. The electro-thermometer which he used in these researches was an improvement on the older instruments of Kinnersley and Harris. Riess repeated and extended the experiments of Coulomb, and effected many improvements in the apparatus for electro-statical experiments. His *Reibungselectricität* is a work of great value, and was for long the best book of reference open to the experimental student. Happily, we have now another in the recently published work of M. Mascart.

Sir William Thomson revolutionized experimental electricity by introducing instruments of precision. Chief among these are his quadrant and absolute electrometers. His portable electrometer and water-dropping apparatus are instruments of great value to the meteorologist in the study of atmospheric electricity, a science which he has done much in other ways to forward. Besides this, we owe to him many valuable suggestions for electrical apparatus and experimental methods, some of which have been carried out by his pupils.

Electro-statical theory.

The theory of statical electricity has made great progress since Poisson's time. Among its successful cultivators we may mention Murphy, (*Electricity*, 1833), and Plana (1845). The latter went over much the same ground as Poisson, extending his results. It was, however, by Green (*Essay on the Application of Mathematical Analysis to the Theories of Electricity and Magnetism*, 1828; or, *Mathematical Papers*, edited by N. M. Ferrers), a self-taught mathematician, that the greatest advances were made in the mathematical theory of electricity. "His researches," as Sir William Thomson has observed, "have led to the elementary proposition which must constitute the legitimate foundation of every perfect mathematical structure that is to be made from the materials furnished in the experimental laws of Coulomb. Not only do they afford a natural and complete explanation of the beautiful quantitative experiments which have been so interesting at all times to practical electricians, but they suggest to the mathematician the simplest and most powerful methods of dealing with problems which, if attacked by the mere force of the old analysis, must have remained for ever unsolved." One of the simplest applications of these theorems was to perfect the theory of the Leyden phial, a result which (if we except the peculiar action of the insulating solid medium, since discovered by Faraday) we owe to his genius. He has also shown how an infinite number of forms of conductors may be invented so that the distribution of electricity in equilibrium on each may be expressible in finite algebraical terms,—an immense stride in the science, when we consider that the distribution of electricity on a single spherical conductor, an uninfluenced ellipsoidal conductor, and two spheres mutually influencing one another, were the only cases solved by Poisson, and indeed the only cases conceived to be solvable by mathematical writers. The work of Green, which contained these fine researches, though published in 1828, had escaped the notice not only of foreign, but even of British mathematicians; and it is a singular fact in the history of science that all his general theorems were rediscovered by Sir William Thomson, Chasles and Sturm, and Gauss (see *Reprint* of Thomson's papers). Sir William Thomson, however, pushed his researches much further than his fellow-laborers. He showed that the experimental results of Sir William Snow Harris, which their author had supposed to be adverse to the theory of Coulomb, were really in strict accordance with that theory in all cases where they were sufficiently simple to be submitted to calculation. He was guided in his earlier investigations by an analogy between the problems involved in steady flux of heat and the equilibrium of electricity on conductors. He showed in 1845 how the peculiar electric polarization discovered by Faraday in di-electrics, or solid insulators subjected to electric force, is to be taken into account in the theory of the Leyden jar, so as to supply the deficiency in Green's investigations. We also owe to Sir William Thomson new synthetical methods of great elegance and power. The theory of electric images, and the method of electric inversion founded thereon, constitute the greatest advance in the mathematical theory of electro-statics since the famous memoir of Green. These he has applied in the happiest manner to the demonstration of propositions which had hitherto required the resources of the higher analysis, and he has also found by means of them the distribution on a spherical bowl, a case of great interest in the theory of partially closed conductors, which had never been attacked or even dreamt of as solvable before. The work of Professor Clerk Maxwell on *Electricity and Magnetism*, which appeared in 1873, has already exerted great influence on the study of electricity both in England and on the Continent. In it is fully given his valuable theory of the action of the di-electric medium. He regards the electrical forces as the result of stress in the medium, and calculates the stress components which will give the observed forces, and at the same time account for the equilibrium of the medium. The striking discovery recently made by Mr. Kerr of Glasgow, of the effect on polarized light exerted by a piece of glass under the action of strong electric force, is of great importance in connection with Maxwell's theory, and realizes a cherished expectation of Faraday, of whom Maxwell is the professed exponent. We must allude here once more to Maxwell's electro-magnetic theory of light, the touchstone of which is the proposition that in transparent media, whose magnetic inductive capacity is very nearly equal to that of air, the di-electric capacity is equal to the square of the index of refraction for light of infinite wave length. Although, as perhaps was to be expected, owing to disturbing influences such as heterogeneity, this proposition has not been found in good agreement with experiment in the case of solids, yet for liquids (Silow, *Pogg. Ann.*, clv., clviii.) and gases (Boltzmann, *Ibid.* clv.) the agreement is so good as to lead us to think that the theory contains a great part of the whole truth.

Absolute units.

In the earlier stages of the science several units were introduced for the measurement of quantities dealt with in electricity. As examples of these we may mention the wire of Jacobi, and the mercury column of Siemens, a metre long, with a section of a square millimetre, which at given temperatures furnished units of resistance; the Daniell's cell, which furnished the unit of electro-motive force, the chemical unit of current intensity, etc. All these units were perfectly arbitrary, and there was no connection of any kind between them. The introduction of a rational system of unitation, based on the fundamental units of time, mass, and length, was one of the greatest steps of our time. The impulse came from the famous memoir of Gauss, *Intensitas Vis Magneticæ Terrestris ad Mensuram absolutam revocata*, 1832. In conjunction with Weber, he introduced his principles into the measurement of the earth's magnetic force. To Weber belongs the credit of doing a similar service for electricity. He not only devised three different systems of such units—the electro-dynamical, the electro-statical, and the electro-magnetic—but he carried out a series of measurements which practically introduced the last two systems. The fundamental research in this subject is to determine in electro-magnetic measure the resistance of some wire from which, by comparison, the electro-magnetic unit of resistance can be constructed. Measurements of this kind were made by Kirchhoff in 1849; more carefully in two different ways by Weber in 1851; by the committee of the British Association in 1863, etc.; by Kohlrausch in 1870; and by Lorenz in 1873. Accounts of these important researches will be found in Wiedemann and Maxwell, and in the collected reports of the British Association on "Electrical Standards." The ratio of the electro-static to the electro-magnetic unit of electric quantity is a velocity (according to Maxwell's electro-magnetic theory of light it is the velocity of light), the experimental determination of which is of the greatest theoretical and practical importance. Such determinations have been made by Weber and Kohlrausch in 1856, by Maxwell in 1868, and by Thomson in 1869. The results are not so concordant as might be desired, but the research is a very difficult one.

For convenience in practice the British Association committee have recommended certain multiples of the absolute unit, to which they have given names—*e. g.*, the Ohm, the Volt, the Farad, etc. These have become current to a great extent among practical electricians in this country. For practical purposes, an empirical standard of electro-motive force has been introduced by Latimer Clarke, whose value in volts is given as 1·457. It is very important, in order to be able to reduce chemical to absolute measure, to know accurately the electro-chemical equivalent of water. Values for this have been found by Weber (1840), Bunsen (1843), Casselman (1843), and Joule (1851). Kohlrausch (1873) made a careful determination of the electro-chemical equivalent of silver, from which the electro-chemical equivalent of water can be calculated.

General Sketch of Phenomena.

Fundamental experiment.

If a piece of glass and a piece of sealing-wax be each rubbed with a dry woollen cloth, it will be found that both the glass and the wax have acquired the property of attracting indiscriminately any small light body in the neighborhood; and it will be further observed, in many cases, that the small bodies, after adhering for a little to the glass or wax, will be again repelled.

These actions have at first sight a likeness to the attractions and repulsions of magnetic bodies, but they are sufficiently distinguished from these—1st, By their origin,—being excited by friction and other causes in a great variety of bodies, whereas magnetic action is powerfully exhibited and communicated only by certain varieties of iron and iron ore, by nickel and cobalt, and by certain arrangements which we shall have to mention by and by; 2d, By the nature of the bodies acted on; for these may be, in the case of excited glass or wax, light particles of any substance, whereas the only bodies powerfully acted on magnetically are either magnets or their equivalents, or iron, nickel, and cobalt; and 3d, By the fact that every magnet has two poles possessing opposite properties, whereas an electrified body may have similar properties in every part of its surface.

If the experiment were carefully tried it would be found that a piece of glass excited as above repels another piece of glass similarly excited, but attracts an excited piece of wax. A convenient way of exhibiting these actions, which also brings under our notice another fact of fundamental importance, is as follows. Two gilt balls of elder pith are fastened to the ends of a light needle of shellac, which is balanced horizontally on a point carried on a vertical stand (fig. 1). To the stand a stop is fixed for convenience, to prevent the needle from spinning more than half round. If we touch the ball A with a piece of excited glass, and B with a piece of excited sealing-wax, and touch a ball C, fastened to a shellac stem, with a piece of excited glass, then C will chase A away till it is brought up by the stop, while it will, on the other hand, attract B. If, again, C be touched with a piece of excited wax, it will attract A and repel B.

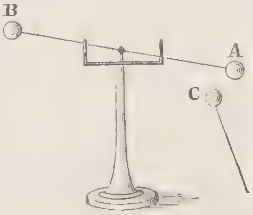

Fig. 1.

Definition of electrification and conduction.

Pieces of glass or wax excited in this way are said to be *electrified*, and the balls which by contact have acquired properties similar to those of the originally electrified bodies are said to be *electrified by conduction*.

It appears from the above experiment that the electrifications of glass and sealing-wax, when rubbed with woollen, have opposite properties, which they communicate to bodies brought into contact with them. A body which has similar electrification to a piece of glass rubbed with woollen is said to be vitreously or positively electrified; a body with similar electrification to a piece of sealing-wax rubbed with woollen is said to be resinously or negatively electrified. The result of the above experiment may then be summarized thus:—

Bodies similarly electrified, whether positively or negatively, repel each other.

Bodies oppositely electrified attract each other.

Conductors and non-conductors.

We have seen that a pith ball becomes, by contact with a positively electrified piece of glass, itself positively electrified. If we take two pith balls, electrify one of them positively, and then touch both simultaneously by a piece of thin wire, suspended by white silk, and test them with the electroscopic needle described above, they will be found both positively electrified; each will repel A and attract B, though less powerfully than the originally electrified ball did before the connection between them was made. The success of the experiment will be found independent of the length or shape of the wire, and will be equally good with silver, gold, iron, lead, or any other metal. But, if we use a thread of glass or shellac to connect the balls, the electrification of the first ball will be found unaltered, and the second will remain neutral—that is, it will not attract or repel another neutral ball, and will *equally attract* both balls A and B, of the electroscopic needle. The difference in the power of transmitting electrical properties from one body to another, or of aiding in electrification by *conduction*, leads us to divide all substances into two classes—conductors, which do very readily, and non-conductors, which do not, or do not very readily, transmit electrification from one body to another. If we connect an electrified conductor by means of another conductor to a very large conducting body, such as the earth, it will be found that so much electrification has been carried away from the small body that it is left sensibly neutral. If, accordingly, we wish a conducting body to preserve its electrification unaltered, we must support it on some non-conducting substance. When thus supported the body is said to be *insulated*, the non-conducting support being called the *insulator*, a name which has on that account been given to non-conductors generally.

Insulation and insulators.

Induction.

We have remarked above that a neutral pith ball attracts equally the positive and negative balls of the electroscopic needle; this leads us to remark, more explicitly than we have hitherto done, that an electrified body in general and in the first instance attracts a neutral or unelectrified body. The explanation of this action is that the originally neutral body in presence of the electrified body becomes itself electrified for the time. It is said to be electrified by *induction*, and it is very easy to show, by using large bodies, not only that the originally neutral body is actually electrified, but that it is oppositely electrified in different parts. Thus (fig. 2) A and B are two bodies suitably insulated and placed one above the other. If B be originally neutral, and A be positively electrified, then the lower end of B will be negatively, and the upper end positively electrified; as may be easily shown by exploring with a small positively electrified pith ball suspended by a dry white silk thread; the little ball will be attracted towards the lower end of B, and repelled from the upper. If we remove the body A, or, which (as we have seen) amounts to the same thing, connect it with the earth, and so "*discharge*" its electrification, we shall find that all traces of electrical action in B have disappeared—*i.e.*, the small positively electrified pith ball will be *attracted* everywhere; and, if we discharge it too, it will neither be attracted nor repelled anywhere.

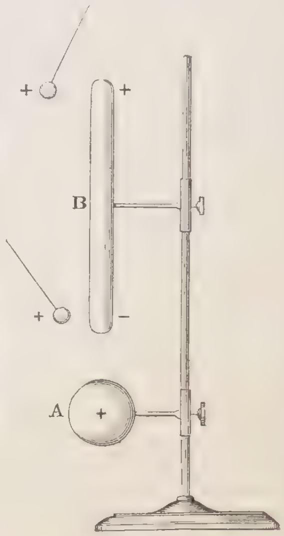

Fig. 2.

Provisional Theory.

Before going further into detail, it will be convenient to give a working theory of electrical phenomena, so far as we have considered them. The use of such a theory at the present stage is to enable us to co-ordinate and classify the results of experiment, and to furnish a few leading principles under which we may group results which appear to be due to a common cause. Such a theory is invaluable as a *memoria technica* for experimental results, and is useful in suggesting directions for experimental inquiry; but in framing it we must be careful to make it contain as little as possible beyond the results of actual experiment, and in using it we must be on our guard against allowing it to prepossess our minds as to what may be the ultimate explanation of the phenomena we are considering.

Use of terms "Electricity," etc.

Following the caution of Coulomb and the example of Sir William Thomson, we shall avoid the use of the term *electrical fluid*, and substitute instead the more succinct and less misleading word *electricity*. We suppose that a body which exhibits electrical properties (as above defined) has associated with its mass a certain quantity of something which, without attempting further definition, we shall call *electricity*. Of our right to use the word *quantity* here we shall give experimental justification by and by, and then the question of the appropriate unit will (*vide infra*, "electric quantity") be discussed. We may suppose that electricity is distributed throughout the whole mass of a body, and speak of electrical "*volume density*," meaning the quantity of electricity in an element of volume divided by the element of volume. We shall also speak of an *element of electricity*, meaning the electricity in an element or very small portion of a body. In certain cases we shall find that electricity resides on the surface of a body; electrical "*surface density*" then means quantity of electricity on an element of surface divided by the element of surface, and element of electricity the electricity on an element of surface.

For shortness, we shall denote positive or vitreous electricity by the mathematical sign +, and resinous or negative electricity by the sign −, remarking that the choice of the signs is arbitrary, and reserving for the present the question of how far we may associate with these signs the corresponding mathematical ideas.

We shall assume that every element of electricity repels every other element of the same sign, and attracts every other element of opposite sign. The precise law of this force will be investigated further on.

This force considered as acting on any element of electricity we shall call an electric force. In perfectly conducting substances electricity moves with perfect freedom under any electro-motive force, however small. In perfect non-conducting substances electricity will not move under any electro-motive force, however great. Any case in nature lies somewhere between these extremes, but into questions of gradation, etc., we do not enter for the present.

When the forces due to other electrical elements acting on the electricity in any element of a body have a resultant, that resultant acts on the element itself, and is called the pondero-motive force, to distinguish it from the electro-motive[1] (or electric) force which tends to move + electricity in one direction and − electricity in the opposite direction.

When a body is neutral, we shall assume that it contains *equal* and *equally distributed* quantities of + and − electricity, and we shall further suppose those to be practically unlimited in amount. A + electrified body is then to be conceived as a body which has excess of + electricity, and a − electrified body as one which has excess of − electricity. Communication of + electricity to a body is in accordance with this to be regarded as equivalent to the abstraction of an equal amount of − electricity, and conversely.

It is easy to see that the above assumptions will explain in a general way the phenomena already described. Thus the + electricity of the electrified pith ball C acting on the + electricity of the ball A of the electroscopic needle repels it, and this force by our assumption is equally exerted on the matter of A, therefore A tends to move away from C, and will do so as long as it is free to move. The action on the − electrified ball B is similarly explained. Conduction and discharge to earth may be explained in a similar manner.

The attraction of an electrified body (+ let us suppose) A on a neutral insulated body B is thus explained. The + electricity on A (fig. 3) attracts the − electricity in B and repels the + electricity, so that, though there is still on the whole as much + electricity as − electricity, yet the distribution is no longer the same, for, the electricity being free to move, the − electricity under the attraction approaches A until the non-conducting air and the attraction of the separated + electricity on B stops it, and the + electricity recedes in similar fashion. When electrical equilibrium has been attained the action of the + electricity of A on the − electricity of B will exceed its action on the + electricity of B, which is on the whole more distant,[2] the electro-motive force on the electricity of B will be on the whole attractive, and hence the pondero-motive force on B will be also attractive.

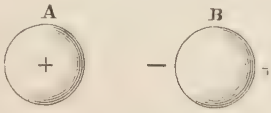

Fig. 3.

The above explanation involves of course the general explanation of *electrification* by *induction.*

Experimental Investigation of Electrical Quantity, Distribution, and Force.

Electroscopes and electrometers.

In what follows we shall suppose that we have an instrument which will serve as an electroscope and to some extent as an electrometer; that is, which shall tell us readily whether a body brought into communication with it is + or − electrified or not at all, and also enable us to tell when one body is more strongly electrified + or − than another.

The gold-leaf electroscope of Bennet or the dry pile electroscope of Bohnenberger will meet these requirements, and have been much used in electrical researches. We shall, however, suppose that we are using the rudimentary form of Thomson's electrometer constructed by Elliott Brothers for lecture-room experiments, which is now much used in England, and answers very well. For a description of these and other electroscopes and electrometers, see article ELECTROMETER.

We shall also assume for the present that we have the means of producing and communicating to any body as much of either kind of electrification as we please, and pass on to consider the data of experiment regarding the distribution of statical electricity in conducting bodies. We are thus at the very outset brought face to face with the idea of electric quantity.

Electric Quantity.

We have to explain how the introduction of the term quantity into electrical science is justified by experiment, and how we can multiply and subdivide quantities of electricity. Although it is no doubt possible to introduce the notion of quantity independently of the *measure* of electric force, yet the most convenient and *practical measure* of quantity depends on the measurement of force, and the absolute electro-static unit of quantity is stated in this way. We are naturally led, therefore, to combine with the study of quantity and distribution the experimental study of the laws of electric force.

We shall have occasion to allude to two leading experimental methods that have been used in investigating the present subject. These might be called the old method and the new.

The old method, which did so much for electrical science in the master hand of Coulomb, depended on the use of the torsion balance and proof plane, both invented by Coulomb himself. This method was used by Reiss and others up to Faraday's time.

Coulomb's torsion balance.

Michell, about Coulomb's time or a little before, first suggested the idea of measuring small forces by the torsion of a wire. He proposed to apply the method to measure the attraction of gravitation between two bodies of moderate size, thus finding the mean density of the earth, and the method was actually carried out by Cavendish; but Coulomb was in all probability unaware of Michell's suggestion. He made careful preliminary experiments (the first of the kind) on the torsion of wires, and found that the couple required to twist a straight wire through a given angle varies as the angle of torsion multiplied by the fourth power of the diameter of the wire directly, and as the length of the wire inversely (*Mém. de l'Acad.*, 1784).

The balance used by Coulomb in most of his experiments is represented in figure 4.

ABDC is a cylinder of glass 1 foot in diameter and 1 foot high. This cylinder is closed by a glass lid pierced centrically and eccentrically by two openings, each about 20 lines wide. Into the middle opening is cemented a glass tube 2 feet high, to the upper end of which is fitted a torsion head; the separate parts of the head are shown larger at the side of the figure. H is a collar cemented to the glass tube; MO a metal disc, divided on the edge into 360 degrees; this disc is fastened to a

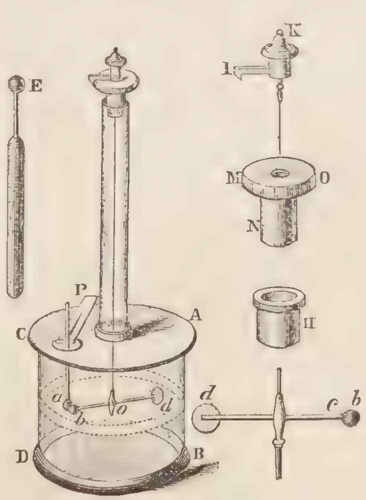

FIG. 4.—Torsion Balance.

---

[1] It might be well to use the term "electric force" here, for "electro-motive force" is afterwards used to mean the line integral of a force (see below, p. 23).

[2] It is here tacitly assumed that the attraction between two elements of electricity decreases as the distance between them increases.

tube N, which slips into the collar H. K is a button whose neck turns easily in a hole in MO; to the lower part of the button is fastened a small clamp, which seizes the wire of the balance. I is an arm with a small projecting piece which slips over the edge of the disc MO. This piece has a fiducial mark on it, which enables us to read off the position of the arm on the graduated edge of MO. The horizontal arm *bd* consists of a silk thread or fine straw covered with sealing wax terminated by a thread of shellac at *b* about 18 lines long, which carries a pith ball 2 or 3 lines in diameter. At the other end of the arm is a vertical disc of oiled paper, which serves as a counterpoise to the pith ball, as a damper to the oscillations, and as an index by means of which the position of the horizontal arm can be read off on a graduation carried round the glass cylinder. The eccentric hole in the cover of the balance allows the introduction of the fixed ball *a*; this is carried on a shellac stem fastened to a clamp P, which by means of fiducial marks can be placed in a fixed position on the cover. The wire in Coulomb's balance was of silver, about 30 cm. long. Its diameter was ·0035 cm., and it weighed about ·003 gm. He found by the method of oscillations that a couple equivalent to the weight of ·17 milligramme, acting at the end of an arm a decimetre long, would keep the wire twisted through 360°.

Besides this form of balance Coulomb used others, some more delicate for electroscopic purposes, and others less so, but of larger dimensions, into which he could introduce electrified bodies of considerable size.

Faraday used Coulomb's balance, and Snow Harris used the bifilar balance, which is a modification of Coulomb's. In the second volume of his *Experimental Researches*, however, Faraday gives a general method of experimenting, which to a great extent has superseded the older method. This may be called the "cage method;" it depends for its success on the use of some delicate instrument for measuring differences of potential; this was supplied by the quadrant electrometer of Sir William Thomson, which has thus completely revolutionized the whole system of electro-static measurement.

Faraday's experiment was as follows (*Exp. Res.*, vol. ii., p. 279):—

Cage method.

Let A (fig. 5) be an insulated hollow conductor with an opening to allow admission to the interior. Faraday used a pewter ice pail,[1] 10½ in. high and 7 in. in diameter. Connect the outside of A with one electrode of an electrometer E, which may for most purposes be the rudimentary form of Thomson's electrometer mentioned above. Connect the other electrode of the electrometer with the earth. If now we introduce a positively electrified body, say a brass ball C, suspended by a white silk string, we shall find that the electrometer needle is deflected through a certain angle, the spot of light going a certain distance to the right, say, of the scale. It will be found that, provided the ball C is more than a certain depth (about 3 in. in Faraday's experiment) below the mouth of the pail, no further motion of the ball, right or left, up or down, will affect the indications of the electrometer. It will also be found that the same indications will be got to whatever point of the *outside* of the pail the electrometer wire is attached. If we diminish or increase the + electrification of C, the electrometer deflection will diminish or increase accordingly. If we introduce a negatively electrified ball C′, the deflection will be to the left, and everything else as before. If C gives a certain positive (right) deflection, and C′ an equal (left) deflection, then if we introduce C and C′ together, the deflection will be zero. If C and C′ be both + electrified and give equal + deflections, then introduced together they will give a double + deflection, and if three such balls, all giving equal + deflections, be introduced together, they will give a treble + deflection.

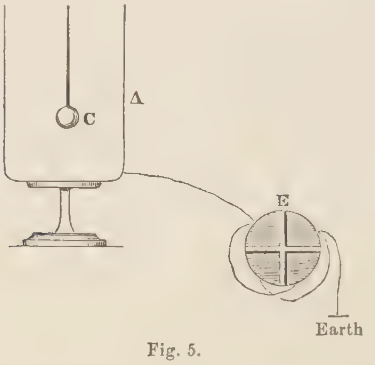

Fig. 5.

It is obvious that this experiment of Faraday's not only gives a very ready test of the electrical state of bodies, but at once suggests the notion of electrical quantity, and a theoretically possible electro-static unit. Suppose, in fact, we take for our test the deflection of a Thomson's electrometer of given sensibility, then we might specify as a unit of electrical quantity the quantity of + electricity on or in a brass ball of given size, which will produce with a given cage a certain given deflection of the electrometer.

To make this definition useful we must have the means of transferring a given charge from one body to another, and charging a body with any multiple or submultiple of our unit, and of charging a body with any multiple or submultiple of the unit of negative electricity, which we may define as the quantity of − electricity which will just annul the action of the unit of + electricity in the electric cage.

All these requirements may be satisfied by suitably modifying Faraday's experiment.

We saw that we might move the ball about in the middle of our electric cage without affecting the electrometer deflection; we find, moreover, that when we withdraw the electrified ball without touching the cage, the needle returns to zero. If, however, before withdrawing the ball we cause it to touch the inside of the cage, the electrometer deflection remains the same as before, and after the ball has been removed the deflection is still the same, while if we examine the ball, we find that all traces of electrification have disappeared.

To transfer a given charge.

To transfer a given quantity of electricity.—If we provide ourselves with two cages, a large one G, and a small one H, and take a ball C, electrified positively with unit quantity as above defined, then testing C in cage G, in connection with the electrometer, we get a certain deflection D. If now we transfer the electrification of C to H, by the process just described, and then put H inside G, we shall get the same deflection D as before. It appears, therefore, that we can transfer electrification from one body to another without loss; we thus fulfil one of our requirements, and give an additional justification of the use of the word quantity in the present case.

Multiple or submultiple of unit charge.

To get any multiple or submultiple of the electric unit.—We may repeat the process above performed on the small cage H by touching its inside with the ball C, again electrified to unit quantity. All the electrification will pass to H as before, and if we now test H in G we shall get a deflection 2 D. We can in this way get any multiple we please of the unit charge. If we take the electrified brass ball C and touch it by a perfectly equal neutral ball C′, on introducing C into G we shall get deflection ½ D; if we touch C again by C′, previously rendered neutral, we shall get deflection ¼ D, and so on; if we had touched C *simultaneously*, as in fig. 6, with two equal neutral balls, we should have got deflection ⅓ D, and so on. We can thus get any submultiple of our unit charge.

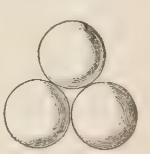

Fig. 6.

To get a given multiple and submultiple of the negative unit.—This is possible when we can get a quantity of − electricity, which will just destroy the action of a given quantity of + electricity in the electric cage. If we introduce our given quantity of + electricity into the cage H, without allowing the conductor carrying it to touch the cage, and at the same time put the outside of the cage in communication with the ground, then if we remove the conductor with the given quantity of + electricity and put it in G, it will give the same + deflection as before, while H tested in the same way will give a negative deflection exactly equal to the former, and if both be introduced together there will be no deflection. We can, therefore, in this way get a − quantity equal and opposite to a given + quantity.[2]

---

[1] A cylinder of wire gauze will answer equally well, and allows the experimenter to see better what he is doing. Such a cylinder we shall call for shortness an "electric cage."

[2] The substance of the above and a good deal of what follows is taken from Maxwell's *Electricity and Magnetism*, vol. i. We recommend the student to read his remarks on quantity, § 35, venturing to suggest, as an illustration of the transmission of energy by action at a distance, the case of two bar magnets, in which the energy of vibration is transmitted and retransmitted periodically. See Tait's *Recent Advances in Physical Science*, p. 179.

Electrical Distribution.

Experiments had been made before Coulomb's time to determine what effect the nature of a body has on electrical distribution. Gray and White concluded from an experiment with two cubes of oak, one hollow and the other solid, "that it was the surface of the cubes only which attracted." Le Monnier[1] showed that a sheet of lead gave a better spark when extended than when rolled together. These experiments point to the conclusion that electrical distribution in conducting bodies depends merely on the shape of the bounding surface.

We may make experiments confirmatory of this conclusion with the electric cage. If we electrify a brass sphere A, and then touch it with another sphere B, and test the electrification of B in the cage, we shall find that the amount of electricity taken by B is always the same, whatever its material may be, so long as the radius of its external surface is the same. Experiment is unable to detect any difference in this respect between a solid sphere of lead and the thinnest soap-bubble of the same radius. Coulomb took a large cylinder of wood, in which he made several holes four lines in diameter and four lines deep. Having electrified the cylinder and insulated it, he examined its electrical condition by means of the proof-plane. This instrument, so much used by Coulomb, consisted merely of a small disc of gilt paper (in this case a line and a half in diameter) fastened to the end of a needle of shellac. The disc is applied to any point of a body whose electrification we wish to test so as to be in the tangent plane to the surface of the body. Assuming for a moment, what we shall by and by prove, that electricity resides on the surface of bodies, it is natural to suppose that the proof-plane, when placed as described, will form part of the bounding surface, and will therefore take up as much electricity as was originally on the part of the surface which it covers. If now we remove the proof-plane in the direction of the normal, keeping it, as nearly as possible, parallel to the surface, the electricity will not leave it; but we shall carry safely away all that it had when in contact with the surface of the body. We may return to the consideration of the proof-plane when we come to study mathematically the laws of electrical distribution.

In the experiment with which we are now concerned, Coulomb used a very delicate balance (a force of $\frac{1}{1000}$ of a milligramme was sufficient to keep the wire twisted through 90°). When the proof-plane was applied to any point of the external surface of the wooden cylinder, and then introduced into the torsion balance, it repelled the electrified ball of the balance with great force. When it was carefully introduced into one of the holes, made to touch the bottom, and then carefully withdrawn so as not to touch the edge of the hole, it produced no appreciable effect on the balance.

Hollow sphere experiment.

Coulomb varied this experiment as follows. He insulated and electrified a hollow sphere of metal (fig. 7), and by carefully introducing a proof-plane through a small opening tested the electrical condition of the interior surface. He found no sensible trace of electricity inside, except very near the edge of the small opening. Hence we conclude that if the sphere had been closed entirely there would have been no electrification inside. Many experiments have been made to illustrate the proposition that electricity resides entirely on the surface of conductors. Franklin put a long chain inside a metal teapot, which he insulated and electrified. When he seized the chain by a hook at the end of a glass rod and pulled it out of the teapot he observed that a pair of pith balls, suspended side by side from the teapot, collapsed more and more as the chain was drawn out, and he concluded that the electrification of the teapot, being now spread over a greater surface, had become weaker.

Franklin's experiment.

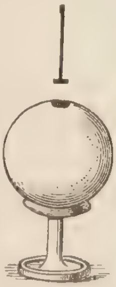

Fig. 7.

Biot's experiment.

The following experiment of Biot's has become classical. A spherical conductor A (fig. 8) is supported on an insulating stem D. B and C are two hollow hemispheres fastened to insulating handles E and F. When these are fitted together they form a sphere somewhat larger than A, with a small hole in it through which the stem D can pass. If we electrify A very strongly, so that when put in the electric cage it powerfully deflects the electrometer, and then close B and C over A, and make either B or C touch it, then separate B and C, and test A, B, and C in the cage, we shall find that all the electricity has gone from A and spread itself over B and C.

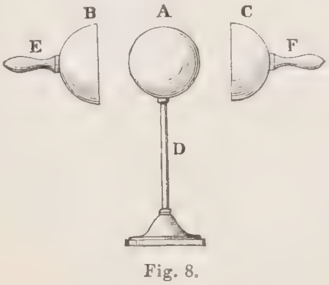

Fig. 8.

Faraday's experiment.

The following is an ingenious experiment of Faraday's, involving the same principle. AB (fig. 9) is a wire ring supported on an insulating stand; C is a conical muslin bag fitted to the ring with two strings fastened to the vertex of the cone, giving the experimenter the means of quickly turning the bag inside out. If the bag be electrified in the first position in the figure and tested with the proof-plane and electric cage, it will be found that the outside only is electrified. If we turn the bag inside out and test it, we shall find as before that what is now the outside, and was formerly the inside, is alone electrified. The electricity has thus passed through the bag so as to be on the outside in both cases.

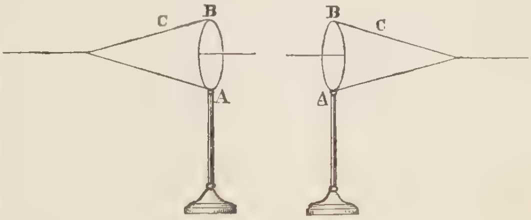

Fig. 9.

Before leaving for a time the question of the distribution of electricity on conductors, it may be well to warn the student to accept with due reserve the proposition that electricity resides entirely on the surface of conductors and to remind him that such a proposition is from the nature of the case incapable of direct experimental proof, for we cannot operate in the substance of a mass of metal. Some of the experiments we have quoted bear more directly on the question than others. Coulomb's experiment, for instance, shows, strictly speaking, merely that electricity avoids cavities and re-entrant angles. Again, in Faraday's experiment with the linen bag, we have not clearly defined what we mean by the outside of the body. The proposition has on the whole been suggested rather than proved. Its meaning will become clearer as we go more and more into the theory of distribution,[2] and we shall meet with it by and by as one of the first propositions in the mathematical theory.

Laws of Electric Force.

Before proceeding to give an account of Coulomb's quantitative experiments on electrical distribution, we shall describe shortly the methods by which he arrived at the laws of electric force, and did for electricity what Newton did for astronomy, *i.e.*, laid the foundation for a mathematical theory of the subject based on the hypothesis of *action at a distance*.

Experimental determination of the elementary law of force.

In this research Coulomb used the form of balance which we described above. The clamp holding the fixed ball of the balance is so adjusted that the centre of the ball falls in a horizontal line through zero of the graduation on the glass cylinder and the prolongation of the suspending wire; the torsion button is turned till its arm is at zero; the disc, button and all, is then turned till the disc on the arm and the centre of the movable ball are in a line with the zero of the lower graduation. The fixed ball, which had been removed to allow of the last adjustment, being replaced, and the movable ball having come to rest in contact with it, both are electrified by means of a small metal ball carried on an insulating stem of shellac. The balls repel each other, and the movable ball takes up a certain position of equilibrium; the corresponding angle is read off. The torsion button is then turned through an angle which is noted, so as to bring the balls nearer together. The new position of the beam is again read off; this may be repeated a third time. We are then in possession of data from which we can draw conclusions as to the law of electrical force at different distances.

---

[1] Mascart, t. i. p. 90.

[2] One additional caution may be useful, viz., not to confound this proposition with another of fundamental importance, of which we can give direct experimental proof of the most conclusive nature "that there is no electrical action inside a hollow conductor containing no charged bodies."

Let us assume that the force between two elements of positive electricity (supposed collected at two points, technically speaking, "regarded as physical points") varies inversely as the square of the distance between them. It will be shown in the mathematical theory that two spheres *uniformly*[1] electrified, as we shall at present assume the two balls in the balance to be, repel each other, as if their electricity were collected at their centres.

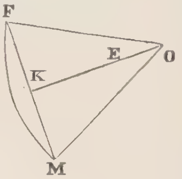

Fig. 10.

Let ϵ be the angle of equilibrium in any case, τ the angle of torsion. O (fig. 10) is the centre of the beam, F and M the centres of the fixed and movable ball (we suppose OF = OM); OK is perpendicular to FM. Then $FM^2 \propto \sin^2\frac{\epsilon}{2}$. Hence, moment of the force on M about O $\propto \frac{\cos\frac{\epsilon}{2}}{\sin^2\frac{\epsilon}{2}}$, and the torsional couple $\propto \tau + \epsilon$.

Hence, in the three cases the value of $(\tau+\epsilon)\sin\frac{\epsilon}{2}\tan\frac{\epsilon}{2} = A$ (say) must be the same, if the law of the inverse square agree with the experiments.

Coulomb made many experiments of the kind we have described. The following is the result which he has given of one such:—

	Observed.	Calculated.	Difference.
τ	ϵ	ϵ	
0	36° 0′	36° 0′	
126°	18 0	18 6	6′
567	8 30	9 4	34

The third column is obtained from the two preceding. A is calculated by putting $\tau = 0$ and $\varepsilon = 36°$ in the formula

$$(\tau + \varepsilon)\sin\frac{\varepsilon}{2}\tan\frac{\varepsilon}{2} = A\,.$$

Then using this value of A and the observed value of τ, the formula is employed to find ε in the two second cases. The agreement between the observed and calculated values of ε is the test of the truth of the law we have assumed. The agreement in the second line is as good as can be expected when possible errors of experiment are considered. It will be seen, moreover, that the calculated is in excess of the observed value, which is what we ought to expect, owing to the loss of electricity which goes on during the time consumed in the experiment. That there is such a loss may be proved experimentally by simply leaving the movable ball to itself after any of the three operations; it will be seen to move slowly towards the fixed ball. We shall return hereafter to this loss of electricity, with regard to the exact nature of which authorities are not quite agreed.[2] In the third line the agreement is less good, but here the proximity of the balls renders the supposition of uniformity no longer even approximately allowable. The mutual repulsion tends to drive the electricity on each ball farther from the other ball, and thus the action between the balls is as if the electricity on each were collected at points beyond the centre, so that the observed repulsion must be less than that calculated on the supposition of uniformity of distribution.

Law of attraction tested by method of oscillations.

Coulomb also made experiments with the torsion balance to test whether the law of the inverse square applies to the attraction as well as to the repulsion of electrified bodies. His experiments confirmed the law; but the difficulty of operating is much greater in this case than in the former. He therefore adopted another method of experimenting. A small conducting disc was fixed normally on the end of a small shellac needle, which was hung up, so as to be horizontal, on a fibre of raw silk attached to a horizontal scale. An insulated conducting globe was set up with its centre in the same vertical plane as the scale, and in the same horizontal plane as the centre of the small disc. The globe and disc were oppositely electrified, and the period of oscillation of the needle was found by observing the duration of 15 swings. The time of oscillation follows the pendulum law, and varies inversely as the square root of the force acting on the needle, hence the duration of 15 oscillations will vary inversely as the square root of the force, *i.e.*, directly as the distance between the centres of the globe and disc, if the law of the inverse square hold. Coulomb's experiment gave the following results:—

Distance of centres of globe and disc.	Duration of 15 oscillations.	Ratio of distance to duration.
9	20	2·22
18	41	2·28
24	60	2·50

The numbers in the third column ought to be all equal. The deviations from equality are not greater than can fairly be explained by loss of electricity and errors of observation.

Coulomb also investigated, both by means of the torsion balance and by the method of oscillations, the relation between electric force and quantity.

He electrified the two balls of the torsion balance by simultaneous contact with another ball, and observed the angle of equilibrium; he then halved the quantity on the fixed ball by touching it with an equal neutral ball, and reduced the torsion till the angle of equilibrium, and, in consequence, the distance between the balls was the same as before; he found the torsional couple in the second case to be somewhat less than half what it was in the first. He therefore concluded that the force between two elements of electricity varies as the product of the quantities.

Coulomb's experiments were repeated, and his results confirmed by Riess,[3] and by Marié-Davy.[4] Experiments which, when properly interpreted, lead to the same results, were made by Snow Harris,[5] and by Egen.[6]

We have then arrived at this general law of electric force:—

Statement of law.

If two quantities q, q' of electricity be supposed collected at two points, whose distance is d, the force between them acts in the straight line joining the points and $\propto \frac{qq'}{d^2}$.

So far, this law might be merely an approximation to the truth. Later on, however, it will be seen to be logically deducible from experiments which in delicacy infinitely surpass those just described. The law of Coulomb is in fact established as certainly as the law of gravitation itself.[7]

Definition of absolute electro-static unit.

By means of the law now given the *unit of electrical quantity* can be defined in a satisfactory and practical manner. This unit we now state to be *that quantity of positive electricity which, when collected into a point, repels with unit of force an equal quantity similarly collected into a point at unit distance from the former.*

If we take centimetre, gramme, and second as our units of length, mass, and time, the unit force will be that force which in a second generates in a gramme of matter a velocity of a centimetre per second.

---

[1] This condition is not absolutely satisfied in any experiment; it is approximately satisfied in Coulomb's experiment.

[2] This is only one of the many experimental difficulties which beset the use of the torsion balance, one of the most difficult of all instruments to use successfully. To appreciate the skill and sagacity of Coulomb in this and other matters, the student must read more detailed accounts (Riess and Mascart, or *Mémoires de l'Acad.*, about 1785) of his labors than we can give here. He will be richly repaid for his trouble. Nothing is better calculated to rouse the failing enthusiasm of the tyro in experimental electricity than a perusal of the works of Coulomb, unless it be to read the *Experimental Researches* of Faraday.

[3] *Reibungselectricität*, Bd. i. p. 94.

[4] Mascart, i. p. 67.

[5] *Phil. Trans.*, 1834 and 1836. In connection with which we call the attention of the student to the classical paper of Sir W. Thomson, *Reprint of Papers on Electro-statics and Magnetism*, p. 15 *sqq.*

[6] Riess, Bd. i. p 94.

[7] We suppose, of course, that we are dealing always with one and the same di-electric throughout.

The law of electric force between two quantities q and q' now becomes

$$\text{Force} = \frac{qq'}{d^2}.$$

The unit of quantity which we have just defined is called the electro-static unit, in contradistinction to the electro-magnetic unit, which we shall define hereafter.

Since the dimension of unit of force is $[\mathrm{LMT}^{-2}]$, where L,M,T symbolize units of length, mass, and time, we have for the dimension of unit of electrical quantity [Q]

$$[\mathrm{Q}] = [\mathrm{LF}^{\frac{1}{2}}] = [\mathrm{L}^{\frac{3}{2}}\mathrm{M}^{\frac{1}{2}}\mathrm{T}^{-1}].$$

Quantitative Results concerning Distribution.

It has already been indicated that electricity in equilibrium resides on the surface of conducting bodies. We must now review shortly the experimental method by which this surface distribution has been more closely investigated. We shall state here some of the general principles arrived at, and one or two of the results, reserving others for quotation when we come to the mathematical theory of electrical distribution.

The most important experiments are due to Coulomb. He used the proof-plane and the torsion balance. Riess, who afterwards made similar experiments, used methods similar to those of Coulomb.

Allusion has already been made to the use of the proof-plane, and it has been stated that when applied to any part of the surface of an electrified body, it brings away just as much electricity as originally occupied the part of the surface which it covers. If, therefore, we electrify the movable ball of the torsion balance in the same sense as the body we are to examine, and note the repulsion caused by the proof-plane when introduced in place of the fixed ball after having touched in succession two parts of the surface of the body, we can, from the indications of the balance, calculate the ratio of the quantities of electricity on the plane in the two cases, and hence the ratio of the electrical densities at the two points of the surface. We suppose, of course, that the proof-plane is small enough to allow us to assume that the electrical density is sensibly uniform over the small area covered by it. In some of his experiments Riess used a small sphere (about two lines in diameter) instead of the small disc of the proof-plane as Coulomb used it. The sphere in such cases ought to be very small, and even then, except in the case of plane surfaces, its use is objectionable, unless the object be merely to determine, by twice touching the same point of the same conductor, the ratio of the whole charges on the conductor at two different times. The fundamental requisite is that the testing body shall, when applied, alter the *form* of the testing body as little as possible,[1] and this requisite is best satisfied by a small disc, and the better the smaller the disc is. The theoretically correct procedure would be to have a small portion of the actual surface of the body movable. If we could remove such a piece so as to break contact with all neighboring portions simultaneously, then we should, by testing the electrification of this in the balance, get a perfect measure of the mean electric surface density on the removed portion. We shall see that Coulomb did employ a method like this.

There are various ways of using the torsion balance in researches on distribution. We may either electrify the movable ball independently (as above described), or we may electrify it each time by contact with the proof-plane when it is inserted into the balance. It must be noticed that the repulsion of the movable ball is in the first case proportional to the charge on the proof-plane, but in the second to the square of the charge, so that the indications must be reduced differently.

In measuring we may either bring the movable ball to a fixed position, in which case the whole torsion required to keep it in this position is proportional to the charge on the proof-plane (or to its square, if the second of the above modes of operation be adopted), or we may simply observe the angle of equilibrium and calculate the quantity from that. It is supposed, for simplicity of explanation in all that follows, that the former of the two alternatives is adopted, and that the movable ball is always independently charged.

The gradual loss of electricity experienced more or less by every insulated conductor has already been alluded to. This loss forms one of the greatest difficulties to be encountered in such experiments as we are now describing. If we apply the proof-plane to a part of a conductor and take the balance reading, giving a torsion τ_1 say, and repeat the observation, after time t, we shall get a different torsion τ_2, owing to the loss of electricity in the interval. This loss, partly if not mainly due to the insulating supports, depends on a great many circumstances, some of which are entirely beyond even the observation of the experimenter. We may admit, however, what experiment confirms within certain small limits, that the rate of loss of electricity is proportional to the charge, and we shall call $\frac{\tau_1 - \tau_2}{t}$ (the loss per unit of time on hypothesis of uniformity) the coefficient of dissipation (δ). This coefficient, although, as we have implied, tolerably constant for one experiment, will vary very much from experiment to experiment, and from day to day; it depends above all on the weather.

Supposing we have determined this coefficient by such an observation as the above, then we can calculate the torsion τ', which we should have observed had we touched the body at any interval t' after the first experiment; for we have, provided t' be small,

$$\tau' = \tau_1 - \delta t' = \tau_2 + \delta(t - t').$$

In particular, if $t' = \frac{1}{2}t$, we have

$$\tau' = \tfrac{1}{2}(\tau_1 + \tau_2).$$

Coulomb used this principle in comparing the electric densities at two points A and A′ of the same conductor. He touched the two points a number of times in succession, first A, then A′, then A again, and so on, observing the corresponding torsions τ_1, τ_1', τ_2, τ_2', etc., the intervals between the operations being very nearly equal. He thus got for the ratio of the densities at A and A′ the values $\frac{\tau_1 + \tau_2}{2\tau_1}$, $\frac{2\tau_2}{\tau_1' + \tau_2'}$, $\frac{\tau_2 + \tau_3}{2\tau_2'}$, etc. These values ought to be all equal: the mean of them was taken as the best result.

In certain cases, where the rapidity of the electric dissipation was too great to allow the above method to be applied, Riess used the method of paired proof-planes. For a description of this, and for some elaborate calculations on the subject of electrical dissipation, the reader is referred to Riess's work.

The cage method is well adapted for experiments on distribution. The proof-plane, proof-sphere, or paired proof-planes may all be used in conjunction with it. If the cage be fairly well insulated, and a tolerably delicate Thomson's electrometer be used, so that the cage may be made large, and the surface density on its outside therefore small, there will be little loss of the external charge; and the method has this advantage, that dissipation from the proof-plane inside the cage does not affect the result of the measurement in hand, it being indifferent, *qua* effect on the electrometer, whether the electricity inside the cage be on the proof-plane, in the air, or elsewhere, provided merely it be inside. The state of the cage as to electrified air, etc., is easily tested by the electrometer at any time.

Coulomb's Results.—If we electrify a sphere, and test the electrical density at two points of its surface, experiment will show, as would be expected from the symmetry of the body, that the density at the two points is the same. If we test the electric density at any point of a sphere, and then halve its charge by division with an equal neutral sphere, and test the electric density again, we shall find it half what it was before. The electric density at any point is therefore proportional to the whole charge on the sphere, or to the *mean density*, meaning by that the whole charge divided by the whole surface of the sphere.

If, instead of a sphere, we operate with an ellipsoid generated by the revolution of an ellipse about its major axis, we shall find that the electric density is not uniform as in the case of the sphere, but greater at the sharp ends of the major axis than at the equator, and the ratio of the densities increases indefinitely as we make the ellipsoid sharper and sharper. This leads us to state a principle of great importance in the theory of electrical distribution, viz., that the electrical density is very great at any pointed part of a conductor.

---

[1] It is evident from what we have advanced here that the use of the proof-plane to determine the electric density at points of a surface where the curvature is very great, *e. g.*, at edges or conical points, is inadmissible. If we attempt to determine the electrical density at the vertex of a cone by applying a proof-sphere there, as Riess did, we shall very evidently get a result much under the mark, owing to the blunting of the point when the sphere is *in situ*. We should, on the other hand, for an opposite reason, get too large a result by applying a proof-plane edgewise to a point of a surface where the curvature is continuous.

If we determine the ratio of the densities at two points of an ellipsoid[1], diminish the charge, and redetermine the same ratio, we shall find that, although the actual densities are diminished, the ratio remains the same; and if we determine the density at any point of the ellipsoid, and then halve its charge by touching it with an equal and similar ellipsoid (they must be placed with their axes in the same straight line, and made to touch at the poles),[2] and redetermine the density at the same point as before, we shall find that the density in the second case is half that in the first. We have in fact, in general, the important proposition that—

The density at any point of a conductor is proportional to the whole charge on the conductor, or, what is the same, to the mean density.

The following case given by Coulomb is interesting; it shows the tendency of electricity towards the projecting parts, ends, or points of bodies. The conductor was a cylinder with hemispherical ends,—the length of the cylinder being 30 inches, its diameter 2 inches. Coulomb gives the following results:—

Distance from end.	Density.
5 in.	1·00
2	1·25
1	1·80
0	2·30

The density at the end is thus more than twice that at the middle.

Other results, taken from Coulomb's unpublished papers, may be found in Biot,[3] Mascart, or Riess. His results for a circular disc we shall quote further on.

Riess made a series of experiments on cubes, cones, etc.; but as these are not of theoretical interest, the calculation in such cases being beyond the powers of analysis at present, and as the use of the proof-plane or sphere with bodies where edges and points occur is not free from objection, we content ourselves with referring to Riess's work for an account of the results.

Coulomb's researches on composite conductors.

Coulomb made a series of experiments on bodies of different forms, which he built up out of spheres of different sizes, or out of spheres and cylinders. These are of very great interest, partly on account of the close agreement of some of the results with the deductions subsequently made by Poisson from the mathematical theory, and partly on account of the clearness with which they convey to the mind the general principles of electric distribution. His method in most cases was to build up the conductor and electrify it with all the different parts in contact, and then, after separating the parts widely, to determine the *mean density* or the whole amount of electricity on each part by the proof-plane or otherwise.

For spheres in contact he found the following results,— S, Q, σ; S', Q', σ' denoting the surface, quantity of electricity, and mean surface density for the two spheres respectively.

$\frac{S'}{S}$	$\frac{Q'}{Q}$	$\frac{\sigma'}{\sigma}$
3·36	3·8	1·09
14.80	11·1	1·33
62·00	37·6	1·65

From this it appears that although the whole amount of electricity on the large sphere is greater than that on the small, yet the mean density for the smaller sphere is greater than for the larger. The above result also affords an experimental illustration of the action of the earth in discharging a conductor connected with it. Comparing the conductor to the small sphere and the earth to the large sphere of 62 times the superficial area of the small one, if we start with charge Q on small sphere, and then put the two in contact, the charge on the small sphere will be reduced to $\frac{1}{38\cdot6}Q$, so that the mean density is diminished in the ratio 1 : 38·6. This ratio increases indefinitely as the ratio $\frac{S'}{S}$ increases. These results are in satisfactory agreement with Poisson's calculations. Coulomb was led by his observations to assign 2 as the limit of the ratio of the mean densities when the ratio of the diameters of the spheres is infinitely great; the mathematical theory gives $\frac{\pi^2}{6}$ or 1·65.

Coulomb also determined the density at the apex or smaller end of the body formed by two unequal spheres in contact. The following are his results, the mean density of the larger sphere being unity:—

Ratio of radii.	Density at apex.	
	Observed.	Calculated.
1	1·27	1·32
2	1·55	1·83
4	2·35	2·48
8	3·18	3·09
16	4·00	4·21

When two equal spheres are placed in contact the distribution will of course be the same in each; Coulomb found that, from the point of contact up to a point on the surface of either sphere distant from it by about 20°, no trace of electricity could be observed; at 30°, 60°, 90°, 180° respectively, the electric density had the relative values ·20, ·77, ·96, 1·00. When the spheres are unequal, the distribution is no longer alike on each. On the small sphere it is less uniform, and the density at the point of the small sphere diametrically opposite the point of contact is greater than anywhere else on the body. The distribution on the larger sphere is more uniform than on the smaller, and the more unequal the spheres are the more uniform is the distribution on the larger, and the smaller the unelectrified part in the neighborhood of the point of contact.

The following results of Coulomb are useful illustrations of distribution on elongated and pointed bodies:—

Three equal spheres (2 in. diameter) in contact, with their centres in the same straight line: the mean densities were 1·34, 1·00, 1·34 on the spheres 1, 2, and 3 respectively.

Six equal spheres as before: mean densities on 1, 2, and 3 = 1·56, 1·05, 1·00.

Twelve equal spheres: mean densities on 1, 2, and 6 = 1·70, 1·14, 1·00.

Twenty-four equal spheres: mean densities on 1, 2, and 12 = 1·75, 1·07, 1·00.

Large (8 in. diameter) sphere with four small (2 in.) spheres applied to it, all the centres in line: the mean density on large sphere being 1, that on the small one next it was ·60, that on the extreme small one 2·08.

Large sphere 1, and twenty-four (2 to 25) small ones: mean densities on 1, 2, 13, 24, 25 = 1·00, ·60, 1·28, 1·46, 2·17.

MATHEMATICAL THEORY OF ELECTRICAL EQUILIBRIUM.

We take as the basis of our theory the assumptions already laid down under the head Provisional Theory, and in addition the precise elementary law of electrical action established by Coulomb. We shall also suppose that we have only perfect conductors and perfect non-conductors to deal with, the medium being in all cases the same, viz., air. When we have to deal with electrified non-conductors we shall suppose the electrification to be rigid, *i. e.*, incapable of disturbance by any electric force we have to consider.

In our mathematical outline we have in view the requirements of the physical more than the mathematical student, and shall pass over many points of great interest and importance to the latter, for full treatment of which we must refer him to original sources, such as the classical papers of Green, the papers of Sir William Thomson, and the works of Gauss. Of peculiar interest mathematically is the elegant and powerful memoir of the last—*Allgemeine Lehrsätze in Beziehung auf die im verkehrten Verhältnisse des Quadrats der Entfernung wirkenden Anziehungs- und Abstossungskräfte*, in which will be found detailed discussions of the continuity of the integrals used in the potential theory, etc. The works of Green and Thomson are too well known in this country to require farther remark.

---

[1] We suppose in all these experiments that we are dealing with a single body, sufficiently distant not only from all electrified bodies but from all neutral conductors to be undisturbed by them. This condition is essential.

[2] It would not do to make the pole of one touch the equator of the other, or to place them otherwise unsymmetrically.

[3] *Traité de Physique.*

Definitions.

When, in what follows, we speak of the *electric field*, we mean simply a portion of space which we are considering with reference to its electrical properties; it will be found conducive to clearness to regard that space as *bounded*. In general the natural boundary would be the walls of the experimenting room; but, for mathematical purposes, we shall, unless the contrary is stated, suppose our field to be bounded by a sphere of radius so great that the action at a point on its circumference due to an electrified body in the field is infinitely small.

The *resultant force* at a point in the electric field is the force which would be exerted on a unit of + electricity placed there without disturbing the electrical distribution elsewhere. It is plain that the resultant force has a definite magnitude and direction at every point in the field, and consequently is in modern mathematical language a *vector*. A curve drawn in the field such that its tangent at every point is in the direction of the resultant force at that point is called a *line of force*. We can draw such a line through every point of space, and if we suspend at any point a small conducting needle, it is obvious, from what we have already laid down about induction, that it will take up a position very nearly parallel to the line of force; so that if we start from any point and carry the centre of the needle always in the direction in which the needle points, we should trace out a line of force.

The *potential* at any point is the work done by a unit of + electricity in passing from that point to the infinitely distant boundary of the electric field, the electric distribution being supposed undisturbed. It is usual to call the infinitely distant boundary a place of zero potential. Zero is to be understood in the sense of "point or position from which we reckon."[1]

Force in terms of V.

Consider two points P, Q, infinitely near each other in the field, and draw a curve from P passing through Q to ∞. Then, if F be the component parallel to PQ of the resultant force at P, we have by our definition

$$\mathrm{F.PQ} = \mathrm{V_P} - \mathrm{V_Q};$$

or in differential notation

$$\mathrm{F}ds = -d\mathrm{V},$$

hence

$$\mathrm{F} = -\frac{d\mathrm{V}}{ds}, \quad . \quad . \quad . \quad (1)$$

and

$$\mathrm{V} = \int_{\mathrm{P}}^{\infty} \mathrm{F}ds = \int_{\mathrm{P}}^{\infty} (\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz), \quad . \quad (2)$$

where V denotes the potential at P, and X, Y, Z the components parallel to the co-ordinate axes of the resultant electric force. We clearly have as particular cases of (1)

$$\mathrm{X} = -\frac{d\mathrm{V}}{dx} \qquad \mathrm{Y} = -\frac{d\mathrm{V}}{dy} \qquad \mathrm{Z} = -\frac{d\mathrm{V}}{dz}. \qquad (3)$$

We may remark that, in all cases which we shall consider at present, the work done in passing from any point to any other point is the same whatever the intermediate path of our exploring unit. Hence V as above defined is a single valued function, and the formula (3) gives the components of resultant force when V is known.

The work done by a unit of + electricity in passing by any path from P to Q is called the *electro-motive force* from P to Q; it is obviously equal to the difference of the potentials at the two points. Thus

$$\mathrm{V_P} - \mathrm{V_Q} = \int_{\mathrm{P}}^{\mathrm{Q}} (\mathrm{X}dx + \mathrm{Y}dy + \mathrm{Z}dz) \quad . \quad (4)$$

is the electro-motive force from P to Q.

Expression of V in terms of definite integrals.

Suppose we concentrate m units of electricity at any point P, and require the potential due to this at a point Q, distant D from P. Applying (2), and, since any path to ∞ may be chosen, taking the integral along the production of PQ to ∞, we get

$$\mathrm{V} = \int_{\mathrm{D}}^{\infty} \frac{m}{r^2}\,dr = \frac{m}{\mathrm{D}}. \quad . \quad . \quad . \quad (5)$$

If we have any number of discrete points with charges m_1, m_2, m_3,...... at distances D_1, D_2, D_3,...... from Q, since the work done by the exploring unit under the action of the whole is got by adding up the work done under the action of each part separately, we clearly have

$$\mathrm{V} = \frac{m_1}{\mathrm{D}_1} + \frac{m_2}{\mathrm{D}_2} + \text{etc.} = \Sigma\frac{m}{\mathrm{D}}. \quad . \quad . \quad (6)$$

From this we may pass to the case of a continuous volume distribution. If ρ be the volume density at the point $\xi\eta\zeta$, and V the potential at xyz, we have

$$\mathrm{V} = \iiint \frac{\rho\,d\xi d\eta d\zeta}{\mathrm{D}}, \quad . \quad . \quad . \quad (7)$$

where D denotes $+\sqrt{(\xi - x)^2 + (\eta - y)^2 + (\zeta - z)^2}$, and the integral is to be extended over every part of the field where there is any charge,—or, which is the same thing, over the whole field, on the understanding that $\rho = 0$ where there is no charge.

If, as will generally be the case, the electricity is distributed on a surface in such a way that on an element $d\mathrm{S}$ of surface there is a quantity $\sigma d\mathrm{S}$ of electricity, where σ is a finite surface density, then

$$\mathrm{V} = \iint \frac{\sigma d\mathrm{S}}{\mathrm{D}}, \quad . \quad . \quad . \quad (8)$$

where D has the same meaning as before, and the integral is extended all over the electrified surface or surfaces.

Continuity of V.

We may make here the important remark that, so long as ρ or σ is not infinite, the integrals in (7) and (8) are finite and continuous. This depends on the fact, which we cannot stop to prove, that the part of the potential at P, contributed by an infinitely small portion of electricity surrounding P, is infinitely small.

In practice, therefore, the electric potential is always continuous; for although we may in theory speak of discrete points and electrified lines where finite electrification is condensed into infinitely small space, yet no such cases ever occur in nature. It may also be shown for any electrical system of finite extent, that, as the distance of P from O, any fixed point at a finite distance from the system is increased indefinitely, the potential at P approaches more and more nearly the value $\frac{\mathrm{M}}{\mathrm{D}}$, where M is the algebraical sum of all the electricity in the system, and D the distance of P from O. Hence at any point infinitely distant from O, $\mathrm{V} = 0$.

We next proceed to prove the following proposition, which will form the basis of the subsequent theory:—

Surface integral of electric induction.

The surface integral of electric induction taken all over the surface inclosing any space is equal to 4π *times the algebraical sum of all the electricity in that space.*

By the electric induction across any element of the surface (taken so small that the resultant force at every point of it may be regarded as uniform) is meant the product of the area of the element into the component of the resultant force in the direction of the normal to the element which is drawn outwards with respect to the inclosed space. Thus $\delta\mathrm{S}$ being an element of surface, ϵ the angle between the positive direction of the resultant force R and the outward normal ν, and E the sum of all the electricity in the inclosed space, the proposition in symbols is—

$$\iint \mathrm{R}\cos\epsilon\,\delta\mathrm{S} = 4\pi\mathrm{E}. \quad . \quad . \quad . \quad (9)$$

We shall prove it in the manner most naturally suggested by the theory of electrical elements acting at a distance, by first showing that it is true for a single element e either outside or inside the surface. Let us suppose e to be at a point P, fig. 11, within S, which for greater generality we may suppose to be a re-entrant surface. Draw a small cone of vertical solid angle $d\omega$ at P, and let it cut the surface in the elements QR, Q′R′, Q″R″; let the outward normals to these be QM, Q′M′, Q″M″. The elements of the surface integral contributed by QR, Q′R′, Q″R″ are obviously $\frac{\mathrm{QR}\,e\cos e}{\mathrm{PR}^2}$,

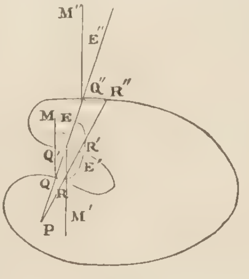

Fig. 11.

---

[1] It may be well here to warn the reader that measurement of potential is relative, just as much as measurement of distance is, and to caution him against the fallacious idea of absolute zero of potential.

etc.; but $QR = \frac{d\omega PR^2}{\cos\epsilon}$, $QR' = -\frac{d\omega PR'^2}{\cos\epsilon'}$, and $Q''R'' = \frac{d\omega PR''^2}{\cos\epsilon''}$; hence the three elements of the integral becomes $+ed\omega$, $-ed\omega$, $+ed\omega$; and the sum is $ed\omega$. Adding now the contributions from all the little cones which fill up the solid angle of 4π about P, we get

$$\iint R\cos\epsilon dS = e\iint d\omega = 4\pi e.$$

Had the point P been outside, the numbers of emergences and entrances would have been equal, the contribution of each cone zero, and on the whole

$$\iint R\cos\epsilon dS = 0.$$

Combining these results, we see that the proposition is true for a single element. Hence, by summation for all the elements, we can at once extend it to any electrical system; for all the elements external to S give zero, and all the internal elements give $4\pi\Sigma e = 4\pi E$.

Equation of Laplace and Poisson.

Let us apply the above proposition to the space enclosed by the infinitely small parallelepiped whose centre is at xyz, and the co-ordinates of whose angles are $x \pm \frac{1}{2}dx$, $y \pm \frac{1}{2}dy$, $z \pm \frac{1}{2}dz$. The contributions to the surface integral from the two faces perpendicular to the x-axis are $-\left(\frac{dV}{dx} + \frac{dx}{2}\frac{d^2V}{dx^2}\right)dydz$ and $\left(\frac{dV}{dx} - \frac{dx}{2}\frac{d^2V}{dx^2}\right)dydz$. Adding these and the four parts from the remaining sides, and equating to $4\pi\rho dxdydz$, which is the $4\pi E$ in this case, we have

$$\frac{d^2V}{dx^2} + \frac{d^2V}{dy^2} + \frac{d^2V}{dz^2} + 4\pi\rho = 0,$$

or, as it is usually abbreviated,

$$\nabla^2 V + 4\pi\rho = \quad . \; . \; . \; . \; . \; . \; . \quad (10)$$

Equation (10), originally found by Laplace for the case $\rho = 0$, and extended by Poisson, has been called the characteristic equation of the potential. It may be applied at any point where ρ is finite and the electric force continuous. It might be shown by examining the integrals representing X, Y, Z, and $\frac{dV}{dx}$, etc., that the electric force is continuous wherever there is finite volume density. Equation (10) may be looked on either as an equation to determine the potential when ρ is given, or as an equation to determine ρ when V is given. We shall have occasion to use it in both ways.

Conditions at an electrified surface.

The characteristic equation cannot be applied in the form (10) when the resultant force is discontinuous. This will be found to be the case at a surface on which electricity is distributed with finite surface density. Let us consider the values of the resultant force at two points, P and Q, infinitely near each other, but on opposite sides of such a surface. Resolve the resultant force tangentially and normally to the surface. If we consider the part of the force which arises from an infinitely small circular disc, whose radius, though infinitely small, is yet infinitely great compared with the distance between P and Q, we see that infinitely little is contributed to the tangential component at P or Q by this disc, while it can be readily shown that the part of the normal component arising therefrom is $2\pi\sigma$, directed *from* the disc *in each* case, when σ is the surface density. Hence, since the part of the resultant force arising from all the rest of the electrified system obviously is not discontinuous between P and Q, the tangential component is continuous when we pass through an electrified surface, but the normal component is suddenly altered by $4\pi\sigma$.

For a thorough investigation of these points the reader is referred to Gauss or Green. We can arrive very readily at the amount of the discontinuity of the normal force by applying (9) to the cylinder formed by carrying an infinitely short generating line round the element dS, so that one end of the cylinder is on one side of dS and the other on the other, the lateral dimensions being infinitely small, but still infinitely greater than the longitudinal. The only part of the integral which is of the order of dS is the part arising from the two ends; hence if N, N′ be the value of the normal components on the two sides of S, we clearly get

$$(N - N')\,dS = 4\pi\sigma dS, \text{ or } N - N' = 4\pi\sigma.$$

If V_1, V_2 denote the potentials on the two sides of S, and ν_1, ν_2 the normals to dS, drawn towards these sides respectively, then we may obviously write our equation

$$\frac{dV_1}{d\nu_1} + \frac{dV_2}{d\nu_2} + 4\pi\sigma = 0. \quad . \; . \; . \; . \quad (11)$$

Written in this form the equation has been called the surface characteristic equation of the potential. It may be looked upon as a surface condition, which must be fulfilled by the values of V on the two sides of an electrified surface on which the surface density σ is given, and where, in consequence, there is discontinuity in the first differential coefficients of V; or it may be looked on as an equation to determine σ when V_1 and V_2 are given.

Surface characteristic equation.

Level surface.

We have seen that we can draw through every point of the electric field a line of force. A surface constructed so that the potential at every point of it has the same value is called an *equipotential or level surface.* We can obviously draw such a surface passing through every point of the field. It is clear, too, that the line of force at every point must be perpendicular to the level surface passing through that point. For since no work is done on a unit of + electricity in passing from one point of a level surface to a neighboring point, there can be no component of the resultant force tangential to the surface; in other words, the direction of the resultant force is perpendicular to the surface. This is expressed otherwise by saying that the lines of force are orthogonal trajectories to the level surface.

Tubes of force.

If we take a small portion of a level surface, and draw through every point of the boundary a line of force, we shall thus generate a tubular surface which will cut orthogonally every level surface which it meets. Such a surface is called a *tube of force.*

Let a tube of force cut two level surfaces in the elements dS and dS'. Apply to the space contained by the part of the tube between the surfaces our fundamental equation (9). We thus get, since there is no normal component perpendicular to the generating lines of the tube,

$$RdS - R'dS' = 0, \quad . \; . \; . \; . \quad (12)$$

provided the tube does not cut through electrified matter between the two surfaces. Here R and R′ denote the resultant force at dS and $d'S$, which are supposed so small that the force may be considered uniform all over each of them. It appears then that *the product of the resultant force into the area of the normal section of a tube of force is constant for the same tube so long as it does not cut through electrified matter; or, what amounts to the same, the resultant force at any point of a tube of force varies inversely as the normal section of the tube at that point.*

Important property of tubes of force $RdS = R'dS'$.

If we divide up any level surface into a series of small elements, such that the product RdS is constant for each element and equal to unity, and draw tubes of force through each small element, then the electric induction through any finite area of the surface is equal to the number of tubes of force which pass through that area; for if n be that number, we have, summing over the whole of the area—

$$\Sigma RdS = n, \quad . \; . \; . \; . \; . \quad (13)$$

the left-hand side of which is the electric induction through the finite area. It is clear, from the constancy of the product RdS for each tube of force, that if this is true for one level surface it will be true for every other cut by the tubes of force. It is evident that the proposition is true for any surface, whether a level surface or not, as may be seen by projecting the area considered by lines of force on a level surface, and applying to the cylinder thus formed the surface integral of electric induction, it being remarked as obvious that the same number of tubes of force pass through the area as through the projection. This enables us to state the proposition involved in equation (9) in the following manner:—

Charge measured by tubes of force.

The excess of the number of tubes of forces which leave a closed surface over the number which enter is equal to 4π times the algebraical sum of all the electricity within the surface.

(*N.B.*—The positive direction of a line of force is that direction in which a unit of + electricity would tend to move along it.) This proposition enables us to measure the charge of a body by means of the lines[1] of force. We have only to draw a surface inclosing the body, and very near to it, and count the lines of force entering and leaving the surface. If the number of the latter, diminished by the number of the former, be divided by 4π, the result is the charge on the body.

---

[1] Here we drop the distinction between line and tube of force. We shall hereafter suppose the lines of force to be always drawn so as to form unit tubes, and shall speak of these tubes as lines of force, thereby following the usual custom.

If we apply (13) to a portion of an equipotential surface so small that R may be considered uniform over the whole of it, we may write

$$R = \frac{n}{dS}; \quad . \quad . \quad . \quad . \quad . \quad . \quad (14)$$

Resultant force measured by lines of force.

or in words:—*The resultant force at any point is equal to the number of lines of force per unit of area of level surface at that point*, meaning thereby the number of lines of force which would pass through a unit of area of level surface if the force were uniform throughout, and equal to its value at the point considered.

We are now able to express by means of the lines of force the resultant force at any point of the field, and the charge in any element of space. The electrical language thus constructed was invented by Faraday, who continually used it in his electrical researches. In the hands of Sir William Thomson, and particularly of Professor Clerk Maxwell, this language has become capable of representing, not only qualitatively but also quantitatively, with mathematical accuracy, the state of the electric field. It has the additional advantages of being well fitted for the use of the practical electrician, and of lending itself very readily to graphical representation.

It will be convenient, before passing to electrical applications, to state here another general property of the potential which follows from our fundamental proposition.

Maximum or minimum potential impossible in free space.

The potential cannot have a maximum or minimum value at a point where there is no electricity.

For if a maximum value were possible, we could draw round the point a surface at every point of which the potential was decreasing outwards; consequently at every point of this surface the normal component of the resultant force in the outward direction would be positive, and a positive number of lines of force would leave the surface. But this is impossible, since, by our hypothesis, there is no electricity within. Similarly there could be no minimum value.

Case of space bounded by level surface.

From this it follows at once that *if the potential have the same value at every point of the boundary of a space in which there is no electrified body, then the potential is constant throughout that space, and equal to the value at the boundary.* For if the potential at any point within had any value greater or less than the value at the boundary, this would be a case of maximum or minimum potential at a point in free space, which we have seen to be impossible.

In order that there may be electrical equilibrium in a perfect conductor, it is necessary that the resultant electric force should be zero at every point of its substance. For if it were not so at any point the positive electricity there would move in the direction of the resultant force and the negative electricity in the opposite direction, which is inconsistent with our supposition of equilibrium. This condition must be satisfied at any point of the conductor, however near the surface. At the surface there must be no tangential component of resultant force, otherwise electricity would move along the surface. In other words, the resultant force at the surface must be normal; its magnitude is not otherwise restricted;[1] for by our hypothesis electricity cannot penetrate into the non-conducting medium.

These conditions are clearly sufficient. We may sum them up in the following single statement:—

Condition of electrical equilibrium.

If the electricity in any conductor is in equilibrium, the potential must have the same value at every point in its substance.

For if the potential be constant, its differential coefficients are zero, so that inside the conductor the resultant force vanishes. Also the surface of the conductor is a level surface, and therefore the resultant force is everywhere normal to it. This constant value of the potential we shall henceforth speak of as the *potential of the conductor.*

Electricity resides on the surface.

Since the potential is constant at every point in the substance of a charged conductor, we have at every point $\nabla^2 V = 0$, and hence by the equation of Poisson $\rho = 0$; that is, there is no electricity in the substance of the conductor. We thus get, as a theoretical conclusion from our hypothesis, the result already suggested by experiment, that electricity resides wholly on the surface of conductors.

If we apply the surface characteristic equation to any point of the surface of a conductor, we get

$$\sigma = -\frac{1}{4\pi}\frac{dV}{d\nu} = \frac{R}{4\pi}, \quad . \quad . \quad . \quad . \quad (15)$$

$\sigma = \frac{R}{4\pi}$.

which gives the surface density in terms of the resultant force and reciprocally.

We may put this into the language of the lines of force by saying that *the charge on any portion of the surface of a conductor is equal to the number of lines of force issuing from it divided by 4π.*

V constant in hollow conductor.

Since the surface of a conductor in electric equilibrium is always a level surface, it follows from what we have already proved about a space bounded by a surface of constant potential, that *inside a hollow conductor the potential is constant, provided there be no electrified bodies within.* This is true, no matter how we electrify the conductor or what electrified bodies there may be *outside.* Hence, if we inclose any conductor A completely within another B, then electrify B, and put A in metallic communication with it, A will not become charged either + or − ; for, A being at the same potential as B, electricity will not tend to flow from the one to the other. This is in reality Biot's[2] experiment with the hemispheres, to which we have already alluded; only the point of view is slightly changed. The most striking experiment ever made in illustration of the present principle is that described by Faraday in his *Experimental Researches.* He constructed a hollow cube (12 feet in the edge) of conducting matter, and insulated it in the lecture-room of the Royal Institution. We quote in his own words the part of his description which bears on the present question:—

> "1172. I put a delicate gold-leaf electrometer within the cube, and then charged the whole by an outside communication, very strongly for some time[3] together; but neither during the charge nor after the discharge did the electrometer or air within show the least sign of electricity. . . . I went into the cube and lived in it, and using all other tests of electrical states, I could not find the least influence upon them, though all the time the outside of the cube was powerfully charged, and large sparks and brushes were darting off from every point of its outer surface."

Indirect evidence for the law of inverse square.

The proposition that the potential is constant inside a hollow conductor containing no electrified bodies may be regarded as one of the most firmly established in the whole of experimental science. The experiments on which it rests are of extreme delicacy. It is of the greatest theoretical importance; for we can deduce from it the law of the inverse square. Taking the particular case of a spherical shell, uninfluenced by other bodies, on which of course the electrical distribution must from symmetry be uniform, it can be demonstrated mathematically that, if we assume the action between two elements of electricity to be a function of the distance between them, then that function must be the inverse square, in order that the potential may be constant throughout the interior. A demonstration of this proposition was given by Cavendish, who saw its importance; a more elaborate proof was afterwards given by Laplace; for a very elegant and simple demonstration we refer the mathematical reader to Clerk Maxwell's *Electricity*, vol. i. § 74. This must be regarded as by far the most satisfactory evidence for the law of the inverse square; for the delicacy of the tests involved infinitely surpasses that of the measurements made with the torsion balance; and now that we have instruments of greatly increased sensitiveness, like Thomson's quadrant electrometer, the experimental evidence might be still further strengthened.

General problem of electrical distribution.

In the problem to determine the distribution of electricity in a given system of conductors, the data are in most cases either the charge or the potential for each conductor. If the conductor is insulated it can neither give nor lose electricity, its charge is therefore given. If, on the other hand, it be connected with some inexhaustible source of electricity at a constant potential, its potential is given. Such a source the earth is assumed to be; and we shall henceforth take the potential of the earth as zero, and reckon the potential of all other bodies with reference to it. If all our electrical experiments were conducted in a space inclosed by a perfectly conducting envelope, the potential of this envelope would be the natural zero of our reckoning.

---

[1] Of course in practice there is an upper limit at which disruptive discharge occurs.

[2] The experiment was first made by Cavendish. There is an account of it in his hitherto unpublished papers.

[3] Faraday was looking for what he called the absolute charge of matter; incidentally the experiment illustrates the point we are discussing.

It will be useful to analyze more closely the distribution on a system of conductors, in order to see how far the above data really determine the solution of the electrical problem. For this purpose the following proposition is useful.

Principle of electrical superposition.

If $e_1, e_2, \ldots\ldots e_n$ be the charges at the points 1, 2, ... n of any system, and V the potential at P, and if V′ be the potential at P due to e_1', e_2', ... e_n' at 1, 2, ... n, then the potential at P due to e_1+e_1', e_2+e_2', ... at 1, 2, ... is $V+V'$. This principle follows at once from the definition of the potential as a sum formed by the mere addition of parts due to all the single elements of the system.

Applied to a system of conductors in equilibrium, it may evidently be stated thus: If $E_1, E_2, \ldots\ldots E_n$ and $V_1, V_2, \ldots\ldots V_n$ be the respective charges and potentials for the conductors 1, 2, 3 .... n in a state of equilibrium, E_1', E_2', ... E_n' and V_1', V_2', ... V_n' corresponding charges and potentials for another state of equilibrium, then E_1+E_1' .... E_n+E_n', V_1+V_1' .... V_n+V_n' will be corresponding charges and potentials for a third state of equilibrium.

Particular case of general problem.

Suppose that in the system of conductors 1, 2, 3, ... n the conductor 1 is kept at potential 1 and all the others at potential zero, then it can be shown that there is one and only one distribution of electricity fulfilling these conditions. Mathematically stated, the problem is to determine a function V, which shall satisfy the equation $\nabla^2 V = 0$ throughout the space unoccupied by conductors, and have the values 1, 0, 0, ... 0 was respectively at each point of the surfaces of 1, 2, ... n respectively.

Consider the integral

$$I = \iiint \left\{ \left|\frac{dV}{dx}\right|^2 + \left|\frac{dV}{dy}\right|^2 + \left|\frac{dV}{dz}\right|^2 \right\} dxdydz, \quad . \quad . \quad (16)$$

where the integration is extended all over the space unoccupied by conductors. If we consider all the values which this integral may have, consistent with the boundary conditions $V = 1$, $V = 0$, ... etc. at the surfaces of 1, 2, ... etc., it is obvious that there must be a minimum value; for the integral is essentially positive, and cannot become less than zero.

$$\text{Now } \delta I = 2\iiint \left(\frac{dV}{dx}\,\frac{d\delta V}{dx} + \text{etc.}\right) dxdydz$$

$$= 2\iiint \delta V \nabla^2 V dxdydz \quad . \quad . \quad . \quad . \quad . \quad . \quad (17)$$

by partial integration. The surface terms vanish, since $\delta V = 0$ at every surface. Hence $\nabla^2 V = 0$ is the condition for a maximum or minimum value of I, and since we know that a minimum value exists, there must be a solution of this equation. It can, moreover, be shown, by a method which we shall apply below to the more general problem, that there is only one solution of $\nabla^2 V = 0$ consistent with the given conditions, and this will of course be that which makes I a minimum. If our mathematical methods were powerful enough to determine V, we might proceed to find the surface density for each conductor by means of the formula $\sigma = -\frac{1}{4\pi}\frac{dV}{d\nu}$; then the charges on the conductors could be found by means of the integral $-\frac{1}{4\pi}\iint \frac{dV}{d\nu} dS$. In very few cases indeed could we actually find these charges; we have, however, demonstrated their existence and shown that our problem is definite.

Coefficients of capacity and induction.

Let these charges on 1, 2, ... n be called q_{11}, $q_{12} \ldots q_{1n}$. Corresponding to the data 0, 1, 0, ... 0 for the potentials of 1, 2, ... n, we should get a series of charges $q_{21}, q_{22}, \ldots\ldots q_{2n}$, and so on; $q_{11}, q_{22}, q_{33} \ldots$ are called the coefficients of self-induction or capacity for the conductors 1, 2, 3, ...; q_{12}, q_{13}, etc., are called the coefficients of induction of 1 on 2, 1 on 3, etc. It is obvious that these coefficients depend solely on the form and relative position of the conductors. It follows, from the principle of the superposition, that, if 1, 2, ... n be at the potentials V_1, 0, 0 ... 0, then the charges on them will be $q_{11}V_1$, $q_{12}V_1 \ldots\ldots q_{1n}V_1$. We may construct then a series of states of equilibrium represented thus:—

Potential,	V_1	0	0	......	0
Charge,	$q_{11}V_1$	$q_{12}V_1$	$q_{13}V_1$	...	$q_{1n}V_1$,
Potential,	0	V_2	0	...	0
Charge,	$q_{21}V_2$	$q_{22}V_2$	$q_{23}V_2$	......	$q_{2n}V_2$,

and so on. Superposing all these, we get a system in equilibrium, in which the potentials are $V_1, V_2, \ldots V_n$, and the charges.

$$\left.\begin{array}{l} E_1 = q_{11}V_1 + q_{21}V_2 + \ldots + q_{n1}V_n \\ E_2 = q_{12}V_1 + q_{22}V_2 + \ldots + q_{n2}V_n \\ \text{Etc.} = \text{etc.} \end{array}\right\} \quad . \quad . \quad (18)$$

It appears therefore that the $2n$ quantities E_1, etc., V_1, etc., are connected by n linear equations; so that when n of them are given, the rest can be determined in terms of these in a definite manner.

Returning then to our general problem, we see that, when either the charge or the potential is given for each conductor, the electrical problem is determinate, and a solution is given by the linear equations of (18). The potential at any point of the field can be written down very easily. Suppose in fact v_1 to be the value at the point P of the function V which we determined in solving the case where the potentials 1, 0, 0, ... 0 are given for 1, 2, ... n, v_2 the corresponding function for the case 0, 1, 0, ... 0, and so on. Then the potential at P in the general case is obviously

$$V = V_1 v_1 + V_2 v_2 + \ldots\ldots + V_n v_n, \quad . \quad . \quad (19)$$

where $v_1, v_2, \ldots v_n$ are all known functions, and $V_1, V_2, \ldots V_n$ are all either given, or determined in terms of given quantities by the equations (18).

It is very easy to show that there is no other solution of the problem than the one we have found.

Suppose in fact that V′ is a function different from V, which satisfies all the conditions of the problem. Consider the function $U = V - V'$, since V and V′ both satisfy the equation $\nabla^2 V = 0$, we have $\nabla^2 U = 0$. Also at surfaces where V is given $U = 0$. At surfaces where V is not given, we have U = constant — constant = constant; and, since in this case the charge will be given, we shall have

$$\iint \frac{dV}{d\nu} dS = \iint \frac{dV'}{d\nu} dS\,; \text{ and therefore } \iint \frac{dU}{d\nu} dS = 0.$$

Now we have

$$\iiint \left\{ \left(\frac{dV}{dx} - \frac{dV'}{dx}\right)^2 + \text{etc.} \right\} dxdydz$$

$$\iiint \left\{ \left|\frac{dU}{dx}\right|^2 + \left|\frac{dU}{dy}\right|^2 + \left|\frac{dU}{dz}\right|^2 \right\} dxdydz$$

$$= \iint \frac{dU}{d\nu} U dS - \iiint U \nabla^2 U dxdydz.$$

The first term vanishes for all the surfaces,—for some because $U = 0$, for others because U is constant and $\iint \frac{dU}{d\nu} dS = 0$; and the second term vanishes because $\nabla^2 U = 0$.

Hence the integral on the left hand must vanish, and that too element by element, since every element is positive. Hence we must have

$$\frac{dV}{dx} = \frac{dV'}{dx}, \quad \frac{dV}{dy} = \frac{dV'}{dy}, \quad \frac{dV}{dz} = \frac{dV'}{dz}.$$

Hence V and V′ can only differ by a constant. But such difference is precluded by the boundary conditions. Hence the functions are identical; in other words, there is but one solution to the problem we have proposed.

It is very easy to show, by methods of which we have already had an example, that the value of V thus found makes the integral

$$\frac{1}{8\pi}\iiint \left(\left|\frac{dV}{dx}\right|^2 + \left|\frac{dV}{dy}\right|^2 + \left|\frac{dV}{dz}\right|^2 \right) dxdydz$$

a minimum. Now, we shall show directly that this integral represents the potential energy of the system. It follows, therefore, that the distribution which we have found is in *stable* equilibrium.

If we solve the equations (18), we shall get

$$\left.\begin{array}{l} V_1 = p_{11} E_1 + p_{21} E_2 + \ldots\ldots p_{n1} E_n \\ V_2 = p_{12} E_1 + p_{22} E_2 + \ldots\ldots p_{n2} E_n \\ \qquad \text{etc.} \end{array}\right\} \ldots\ldots \quad (20)$$

Coefficients of potential.

A set of equations which we might obviously have arrived at by first principles. The physical meaning of the coefficients $p_{1\,1}$, $p_{1\,2}$, and $p_{1\,n}$ is very obvious; they are the potentials corresponding to a state of equilibrium, in which the charges on 1, 2, 3, ... n are 1, 0, 0, . . . 0, and so on. $p_{1\,1}$, $p_{1\,2}$, . . etc., are called coefficients of potential; and, *mutatis mutandis*, all the remarks already made about $q_{1\,1}$, $q_{1\,2}$, etc., apply to them. Many interesting and important theorems have been proved about these coefficients, for which we refer the reader to Maxwell (*Electricity*, vol. i. chap. 2), whose treatment of the subject we have in the main been following. One of these, of great importance, we shall prove here, because it leads us to state a very important general theorem, which we shall have occasion to use again.

Theorem of mutual potential energy.

The mutual potential energy of two electrical systems, A and B, is the work done in removing the two systems to an infinite distance from each other, the internal arrangement of each system being supposed unaltered during the process. It is clear that we may suppose either that A is fixed and B moves off to infinity, or that B is fixed and A moves; the work done in both cases is, by Newton's third law of motion, the same. This is sometimes expressed by saying that *the potential of A on B is the same as that of B on A.*

In fact, the expression for the mutual potential energy is

$$\Sigma\frac{qq'}{\mathrm{D}}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

where q is any element of electricity belonging to A, and q' any element belonging to B, and D is the distance between them, the summation being extended so as to include every pair of elements. We may arrange (21) as follows:—

$$q_1'\Sigma_1\frac{q}{\mathrm{D}} + q_2'\Sigma_2\frac{q}{\mathrm{D}} + \text{etc.},$$

each group belonging to a point in B, or, as we may write it,

$$q_2'\mathrm{V}_1 + q_2'\mathrm{V}_2 + \text{etc., or } \Sigma q'\mathrm{V}.$$

We may also arrange (21) in the form

$$q_1\Sigma_1\frac{q'}{\mathrm{D}} + q_2\Sigma_2\frac{q'}{\mathrm{D}} + \text{etc.},$$

each group belonging to a point in A. Hence we have the following equalities:

$$\Sigma q'\mathrm{V} = \Sigma\frac{qq'}{\mathrm{D}} = \Sigma q\mathrm{V}'. \quad . \quad . \quad . \quad . \quad . \quad . \quad (22)$$

The first and last of these expressions are called respectively the potential of A on B, and the potential of B on A, and this equality explains the statement made above.

The two systems A and B may be different states of equilibrium of the same system, if we choose. In this case we may still farther modify the expression in (22), and write

$$\mathrm{V}_1\Sigma_1 q' + \mathrm{V}_2\Sigma_2 q' + \text{etc.} = \mathrm{V}_1'\Sigma_1 q + \mathrm{V}_2'\Sigma_2 q + \text{etc.}$$

(See Gauss, *l. c.*)

So that we may state the proposition thus:—If E_1, E_2, . . . E_n, V_1, V_2, . . . V_n, and E_1', E_2', . . . E_n, V_1', V_2', . . . V_n' be the respective charges and potentials of the conductors in two different states of equilibrium, then we have

$$\Sigma\mathrm{E}'\mathrm{V} = \Sigma\mathrm{E}\mathrm{V}' \quad . \quad . \quad . \quad . \quad . \quad (23)$$

If we take for the two states of the system

$$\begin{array}{c||c|c|c|c|c|} \frac{\mathrm{E}}{\mathrm{V}} & \frac{q_{1\,1}}{1} & \frac{q_{1\,2}}{0} & \frac{q_{1\,3}}{0} & \frac{\cdots}{\cdots} & \frac{q_{1\,n}}{0} \end{array},$$

and

$$\begin{array}{c||c|c|c|c|c|} \frac{\mathrm{E}'}{\mathrm{V}'} & \frac{q_{2\,1}}{0} & \frac{q_{2\,2}}{1} & \frac{q_{2\,3}}{0} & \frac{\cdots}{\cdots} & \frac{q_{2\,n}}{0} \end{array},$$

equation (23) becomes

$$q_{2\,1} = q_{1\,2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

or, in words, *the coefficient of induction of* 1 *on* 2 *is equal to that of* 2 *on* 1.

External and internal systems.

There is one more general theorem on electrical distribution which, from its great practical importance, deserves a place here. Suppose we take a hollow conductor of any form, place any electrical system inside it, and connect the conductor with the earth, then equilibrium will be established, in such a way that the potential of every portion of the conductor is zero. Now, the potential being zero at all infinitely distant points, we may regard the outside space as inclosed by a surface of zero potential; hence the potential at every point in this space must be the same, and there can be no electrical action anywhere outside.

Again, removing the internal system, let us place any system outside the conductor, and, besides, charge it to any desired extent, keeping it insulated this time. Then the outer and inner surfaces of the conductor will be level surfaces; and, since there is no electricity inside the inner surface, the potential in the interior will be constant. Hence the external system, in a state of equilibrium, exerts no action whatever within. Now we may evidently, without mutual disturbance, superpose such an internal and external system as we have described, and still get a system in equilibrium. It is, moreover, clear that we can in this way satisfy the most general conditions that can be assigned. Hence, since we know that there can be only one solution of the problem of electrical equilibrium, the synthetical one thus obtained represents the actual state of affairs. When, therefore, a hollow conductor with any external and internal systems is in equilibrium, *the equilibrium of the internal is independent of that of the external system.*

Moreover, if we draw any surface *in the substance of the hollow conductor*, no lines of force cross it in one direction or the other; therefore the whole amount of electricity within must be zero; in other words, *the charge on the internal surface of the conductor is equal and opposite to the algebraical sum of the charges on all the bodies within.*

Electrical screens.

These propositions contain the principle of what are called electrical screens, *i.e.* sheets of metal used to defend electrical instruments, etc., from external influences. On the practical efficiency of gratings in this way, see Maxwell (§ 203); on the application to the theory of lightning conductors, see a paper by him in the reports of the British Association for 1876.

If we take the simple case where there is no external system, but only a charge on the hollow conductor, we get a complete explanation of Faraday's ice-pail experiment.

Potential energy of a system of conductors.

The potential energy of a system of charged conductors is the work required to bring them from a neutral state to the charges and potentials which they have at any time. The state of zero potential energy here contemplated is of course that in which there is an equal amount of + and − electricity everywhere in the system, or, as we might put it, the state in which there is no electrical separation. Now if Q denote the potential energy of the system, we have with the notation of (21)

$$\mathrm{Q} = \Sigma\frac{qq'}{\mathrm{D}}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

the summation including every pair of elements in the system. If the system be in equilibrium, then, reasoning as above, it is obvious that $\Sigma\mathrm{EV}$ is just twice $\Sigma\frac{qq'}{\mathrm{D}}$, inasmuch as each pair of elements will come in twice. Hence we get

$$\mathrm{Q} = \tfrac{1}{2}\Sigma\mathrm{EV}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

This is an expression of the greatest importance. We can give it various forms; by means of (18) and (20) we get

$$\mathrm{Q} = \tfrac{1}{2}\sum_{r=1}^{r=n}\sum_{s=1}^{s=n} q_{rs}\mathrm{V}_r\mathrm{V}_s = \tfrac{1}{2}\sum_{r=1}^{r=n}\sum_{s=1}^{s=n} p_{rs}\mathrm{E}_r\mathrm{E}_s \quad . \quad (27)$$

So that Q is a homogeneous quadratic function of the potentials or of the charges. If, therefore, we increase the potentials of *all* the conductors, or the charges of *all* the conductors in any ratio, we increase thereby the potential energy in the duplicate of that ratio.

We can by a transformation, which is a particular case of a theorem of Green's, obtain a very remarkable volume integral for the potential energy of an electrical system.

Green's theorem.

Let V denote the potential at any point in the field. Consider the integral

$$\frac{1}{8\pi}\iiint\left(\overline{\frac{d\mathrm{V}}{dx}}\Big|^2 + \overline{\frac{d\mathrm{V}}{dy}}\Big|^2 + \overline{\frac{d\mathrm{V}}{dz}}\Big|^2\right)dxdydz,$$

where the integration is to be extended throughout the whole of the space unoccupied by conductors. We have by partial integration

$$\iiint\overline{\frac{d\mathrm{V}}{dx}}\Big|^2 dxdydz = \iint\mathrm{V}\frac{d\mathrm{V}}{dx}dydz - \iiint\mathrm{V}\frac{d^2\mathrm{V}}{dx^2}dxdydz,$$

and two similar equations. Hence

$$\frac{1}{8\pi}\iiint\left(\frac{dV}{dx}\Big|^2+\frac{dV}{dy}\Big|^2+\frac{dV}{dz}\Big|^2\right)dxdydz$$
$$=\frac{1}{8\pi}\iint V\frac{dV}{d\nu}dS-\frac{1}{8\pi}\iiint V\Delta^2 V dxdydz,$$

where the surface integration extends over the surface of all the conductors, and it is to be noticed that $d\nu$ is drawn *from the conductor* into the insulating medium. If ρ and σ be volume and surface densities,

$$\sigma=-\frac{1}{4\pi}\frac{dV}{d\nu},\text{ and }\rho=-\frac{1}{4\pi}\Delta^2V.$$

Thus we get

$$\frac{1}{8\pi}\iiint\left(\frac{dV}{dx}\Big|^2+\frac{dV}{dy}\Big|^2+\frac{dV}{dz}\Big|^2\right)dxdydz$$
$$=\tfrac{1}{2}\iint V\sigma dS+\tfrac{1}{2}\iiint V\rho dxdydz. \quad . \quad . \quad . \quad (28)$$

This result includes a more general case than our present one; for it shows that the potential energy of an electrical system is given by the integral on the left-hand side in all cases, whether there is equilibrium or not. It is not even restricted to the case of perfect conductors and perfect nonconductors, for a slight modification of our preliminary statements would include that case as well. At present, however, we have $\rho=0$ everywhere, and V constant at the surface and in the substance of each conductor, so that the right-hand side is simply the expression $\frac{1}{2}\Sigma EV$ which we have already found for the potential energy; we may therefore write

$$Q=\frac{1}{8\pi}\iiint\left(\frac{dV}{dx}\Big|^2+\frac{dV}{dy}\Big|^2+\frac{dV}{dz}\Big|^2\right)dxdydz$$
$$-\frac{1}{8\pi}\iiint R^2dv, \quad . \quad . \quad . \quad . \quad . \quad . \quad (29)$$

R being the resultant force at any point of the field, and dv the element of volume. It is clear that we may if we like extend the integration over the *whole* field, since in the substance of any conductor $R=0$.

Force tending to produce any change of configuration.

When we know the potential energy of an electrical system it is very easy to find the force which resists or tends to produce any change of configuration. Two particular cases are of common occurrence and of considerable interest.

First, let the charges on all the conductors be kept constant. Let the variable which is altered by the supposed change of configuration be ϕ, and let Φ be the corresponding force[1] tending to increase ϕ. Then, since no energy is supplied from without, if we suppose the displacement made infinitely slowly, so that no kinetic energy is generated, we have

$$\Phi\delta\phi+\delta Q=0, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (30)$$

$$\text{or} \qquad \Phi=-\frac{dQ}{d\phi}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (31)$$

Referring to the second of the expressions in (27), we see that this may be written

$$\Phi=-\tfrac{1}{2}\sum_{r=1}^{r=n}\sum_{s=1}^{s=n}E_rE_s\frac{dp_{rs}}{d\phi}.$$

From this it is evident that in similarly electrified states of the same system the force tending to produce a given displacement varies as the square of the electrification. It is important to remark that in the present case the system tends to move so that its potential energy is *decreased*.

Secondly, let us suppose that the potentials of the different conductors are kept constant during any displacement, energy being supplied from without.

We shall suppose the change made in two steps. First, we shall suppose the given displacement to take place while the charges remain constant. On this supposition the force exerted will, to the first order of small quantities, be the same as that exerted when we suppose the potential not to vary; hence

$$\Phi\delta\phi+\tfrac{1}{2}\Sigma E\delta V=0.$$

Next, supply energy from without so that the potentials become again V_1, V_2, etc., . . . and the charges $E_1+\delta E_1$, $E_2+\delta E_2$, etc. The final result will be the same, to first order of small quantities, as if the two changes had been made simultaneously. Now, applying the theorem of mutual potential energy to the two states of our system,

$$\begin{array}{c||c|c} E & E_1 & E_2 \\ \hline V & V_1+\delta V_1 & V_2+\delta V_2 \end{array}\ \ldots \text{ and } \begin{array}{c||c|c} E & E_1+\delta E_1 & E_2+\delta E_2 \\ \hline V & V_1 & V_2 \end{array},\ \ldots$$

we have $\qquad \Sigma(E_1+\delta E_1)(V_1+\delta V_1)=\Sigma(EV),$

hence $\qquad \Sigma E\delta V=-\Sigma V\delta E; \quad . \quad . \quad . \quad . \quad . \quad . \quad (32)$

$$\text{therefore } \Phi=-\tfrac{1}{2}\Sigma E\frac{dV}{d\phi}=\tfrac{1}{2}\Sigma V\frac{dE}{d\phi}=\frac{dQ}{d\phi}(\text{V const.}). \quad . \quad . \quad (33)$$

By (27) this may be written

$$\Phi=\tfrac{1}{2}\sum_{r=1}^{r=n}\sum_{s=1}^{s=n}V_rV_s\frac{dq_{rs}}{d\phi}.$$

The energy supplied from without is

$$\tfrac{1}{2}\{\Sigma(E+\delta E)V-\Sigma E(V+\delta V)\}$$
$$=\tfrac{1}{2}\Sigma\delta EV-\tfrac{1}{2}\Sigma E\delta V=-\Sigma E\delta V=2\Phi\delta\phi=2\delta Q,\text{ by (32).}$$

In other words, when the potentials of a system are kept constant by supply of energy from without, the system tends to move so as to increase the potential energy of electrical separation, and the amount of energy supplied from without is double this increase. If we suspend side by side two balls, each connected with the positive pole of a battery, the other pole of which is connected with the ground, the balls will tend to separate, and in separating they will gain with reference to gravity a certain amount δQ of potential energy; the charges on the balls will also increase to an extent representing an increase of electrical potential energy δQ, and the batteries will be drawn upon for an amount of $2\delta Q$.

Cases where problem has been solved.

The problem of electrical equilibrium has been completely solved in very few cases. We proceed to give a short sketch of what has been done in this way, which may indicate to the reader what is known on this head.

Ellipsoid.

We can deduce the distribution and potential in the case of an ellipsoid from known propositions about the attractions of ellipsoidal shells of gravitating matter.

Consider an ellipsoidal shell, the axes of whose bounding surfaces are (a, b, c) $(a+da, b+db, c+dc)$, where $\frac{da}{a}=\frac{db}{b}=\frac{dc}{c}=\mu$. The potential of such a shell at any internal point is constant, and the equipotential surfaces for external space are ellipsoids confocal with (a, b, c). (See Thomson and Tait, §§ 519 *sqq.*) Hence if we distribute electricity on an ellipsoid (a, b, c) such that its density at every point is proportional to the thickness of the shell formed by the similar ellipsoids (a, b, c) $(a+da, b+db, c+dc)$, the distribution will be in equilibrium. Thus if $\sigma=A\theta\rho$, where θ is the thickness at any point and ρ the volume density of the shell; then the quantity of electricity on any element dS is A times the mass of the corresponding element of the shell; and if Q be the whole quantity of electricity on the ellipsoid, $Q=A$ times the whole mass of the shell. The mass of the shell is $\frac{4}{3}\pi\rho d(abc)=4\pi\mu abc\rho$, therefore $Q=A4\pi\mu abc\rho$. Also $\theta=\mu p$ where p is the perpendicular from the centre of the ellipsoid on the tangent plane. Whence we get

$$\sigma=\frac{Qp}{4\pi abc}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (34)$$

that is, the density at any point varies directly as the distance of the tangent plane at that point from the centre.

Returning again to our ellipsoidal shell, we know that the resultant force at any external point P due to this shell is to that due to a "confocal shell" passing through the point in the ratio of the masses. Let the volume density in the two be ρ, and let the perpendicular on the tangent plane at P to the confocal $(\sqrt{a^2+\lambda}, \sqrt{b^2+\lambda}, \sqrt{c^2+\lambda})$ through P be ω. Then the thickness of the shell at P is $\mu\omega$, and the force at P due to the shell $4\pi\rho\mu\omega$. Hence the force due to the original shell is

$$-\frac{dV}{d\nu}=4\pi\rho\mu\omega\frac{abc}{\sqrt{(a^2+\lambda)(b^2+\lambda)(c^2+\lambda)}}, \quad . \quad . \quad . \quad (a)$$

$d\nu$ being an element of the normal at P. Now if x,y,z be the co-ordinates of P, we have, by differentiation of

$$\frac{x^2}{a^2+\lambda}+\frac{y^2}{b^2+\lambda}+\frac{z^2}{c^2+\lambda}=1,$$

$$\frac{2xdx}{a^2+\lambda}+\frac{2ydy}{b^2+\lambda}+\frac{2zdz}{c^2+\lambda}=\left\{\frac{x^2}{(a^2+\lambda)^2}+\frac{y^2}{(b^2+\lambda)^2}+\frac{z^2}{(c^2+\lambda)^2}\right\}d\lambda.$$

---

[1] Or generalized force component, *i.e.*, the amount of work per unit of ϕ done in increasing ϕ.

Suppose we take dx, dy, dz in the direction of the normal, then $dx = d\nu \frac{\omega x}{a^2 + \lambda}$, etc., and the last equation reduces to

$$d\lambda = 2\omega d\nu\,.$$

Hence from (α) we get

$$-dV = \frac{2\pi\rho\mu abc d\lambda}{\sqrt{(a^2+\lambda)(b^2+\lambda)(c^2+\lambda)}}\,.$$

Integrating this from λ to ∞, and remembering that the potential vanishes at an infinite distance, we get

$$V = 2\pi\rho\mu abc\int_\lambda^\infty \frac{d\lambda}{\sqrt{(a^2+\lambda)(b^2+\lambda)(c^2+\lambda)}}\,. \quad . \quad . \quad . \quad . \quad (\beta)$$

We pass from this to the electrical case by putting for $4\pi\rho\mu abc$, which is the mass of the shell, Q, which represents the quantity of electricity on the ellipsoid. We thus get

$$V = \frac{Q}{2}\int_\lambda^\infty \frac{d\lambda}{\sqrt{(a^2+\lambda)(b^2+\lambda)(c^2+\lambda)}}\,, \quad . \quad . \quad . \quad (35)$$[1]

which gives the potential due to a charge Q on an isolated ellipsoid abc at any point on the confocal ($\sqrt{a^2+\lambda}$, $\sqrt{b^2+\lambda}$, $\sqrt{c^2+\lambda}$). It is obvious that, of the three confocals at P, that is meant which belongs to the same family as (a, b, c), *e.g.*, if (a,b,c) be an ellipsoid, as opposed to a hyperboloid of one or two sheets, then ($\sqrt{a^2+\lambda}$, $\sqrt{b^2+\lambda}$, $\sqrt{c^2+\lambda}$) must be an ellipsoid.

If we put $\lambda = 0$, we get the value of the potential V_0 at the surface. Now $\frac{Q}{V_0}$ is what we have defined above as the capacity of the ellipsoid; we get therefore in the reciprocal of the integral

$$\frac{1}{2}\int_0^\infty \frac{d\lambda}{\sqrt{(a^2+\lambda)(b^2+\lambda)(c^2+\lambda)}}\,, \quad . \quad . \quad . \quad (36)$$

an expression for the capacity of an isolated ellipsoid.

Planetary ellipsoid.

In the particular case of an ellipsoid of revolution, the above integral, which is in general an elliptic integral, can be found in finite terms. In the case of a planetary ellipsoid, $a = b > c$; and we find for the capacity

$$\frac{\sqrt{a^2 - c^2}}{\frac{1}{2}\pi - \varepsilon}\,, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (37)$$

where ε is the least angle whose tangent is $\frac{c}{\sqrt{a^2 - c^2}}$.

Circular disc.

If we make $c = 0$, then $\varepsilon = 0$; and the planetary ellipsoid reduces to a circular disc, the capacity for which is therefore $\frac{2a}{\pi}$, that is, $\frac{1}{1{\cdot}571}$ that of a sphere of the same radius (for the capacity of a sphere is obviously equal to its radius). Cavendish had arrived by experiment at the value $\frac{1}{1{\cdot}57}$ (see Thomson's *Reprint*, p. 180), a very remarkable result for his time. It is very easy, by taking the limit of the right-hand side of (34), to find the expression for the density at a distance r from the centre of the disc; it is

$$\sigma = \frac{Q}{4\pi a\sqrt{a^2 - r^2}} = \frac{V}{2\pi^2\sqrt{a^2 - r^2}}\,. \quad . \quad . \quad (38)$$

Ovary ellipsoid.

In the case of an ovary ellipsoid, $a = b < c$; and the capacity is

$$\frac{2\sqrt{c^2 - a^2}}{\log\left(\frac{c + \sqrt{c^2 - a^2}}{c - \sqrt{c^2 - a^2}}\right)}\,; \quad . \quad . \quad . \quad . \quad (39);$$

from which several limiting cases may be deduced.

Formula (34), applied to a very elongated ovary ellipsoid, shows us that the density at the pointed ends is very great compared with that at the equator. The ratio of the densities in fact increases indefinitely with the ratio of the longest to the shortest dimension. We have in such an infinitely elongated ellipsoid an excellent type of a pointed conductor.

Points and edges.

The effect of a point or an edge on a conductor may be very easily shown by drawing a series of level surfaces, the first of which is the surface of the conductor itself, which has, say, an edge on it. The consecutive surfaces have sharpness of curvature corresponding to the edge, which gets less and less as we recede from the conductor. The level surfaces at an infinite distance are spheres. Tracing, then, any tube of force from an infinite distance, where the sections of all are equal, inwards towards the discontinuity, we see that the section becomes narrower as the curvature of the level surfaces sharpens, and at a mathematical edge the section is infinitely small, and therefore the force is infinitely great. At a mathematical point this is doubly true. At such places the force tending to drive the electricity into the insulating medium becomes infinite. In practice the medium gives way, and disruptive discharge of some kind occurs.

Sphere with given force.

We can find the distribution on a spherical conductor influenced by given forces, such for instance as would arise from *rigidly* electrified bodies in the neighborhood.

The method of procedure would be as follows:—Let U be the potential of the rigidly electrified system alone at any point of the sphere. Then the problem is to determine a function V, which shall satisfy the equation $\nabla^2 V$ at every point of space, and have the value C − U at the surface of the sphere, where C is a constant to be determined by the conditions of the problem. Expand C − U in series of surface harmonics, and let the result be

$$C - U = \gamma_0 + \gamma_1 + \gamma_2 + \quad . \quad . \quad . \quad \text{etc.} \quad . \quad . \quad . \quad (\alpha)$$

Then the value of V is

$$V = \gamma_0 + \gamma_1\frac{r}{a} + \gamma_2\left.\overline{\frac{r}{a}}\right|^2 + \;.\;.\;.\; \text{inside the sphere,} \;.\;.\; (\beta)$$

and
$$V' = \gamma_0\frac{a}{r} + \gamma_1\left.\overline{\frac{a}{r}}\right|^2 + \gamma_2\left.\overline{\frac{a}{r}}\right|^3 + \quad . \quad . \quad . \quad . \quad \text{outside.} \;.\;.\; (\gamma)$$

For these evidently satisfy Laplace's equation, have the given value (α) at the surface of the sphere, and are finite and continuous everywhere. From (β) and (γ), by means of the surface characteristic equation, we can deduce an expression for the density at any point of the sphere, and for the whole charge. If the latter is given we have a condition to determine C; if, on the other hand, the value of the potential of the sphere were given, then this would be the value of C.

Case of two spheres. Poisson's analysis.

The case of two mutually influencing spheres was treated by Poisson in the famous memoir which really began the mathematical theory of electricity. We regret that we cannot afford space for more than a mere sketch of his methods.

Consider the potentials due to the distributions on each sphere. Let a and b be the radii of the two spheres, r and r' the distances of any point P from their respective centres, and μ and μ' the cosines of the angles r and r' make with the line joining the centres of the spheres. Since the distributions are evidently symmetrical about the central line, we can obviously expand the potentials due to each distribution in zonal harmonics relative to the corresponding sphere. Hence, if $4\pi a\phi\left(\mu, \frac{r}{a}\right)$ denote potential due to sphere a at any point inside it, we have

$$4\pi a\phi\left(\mu, \frac{r}{a}\right) = A_0 + A_1Q_1\frac{r}{a} + A_2Q_2\left.\overline{\frac{r}{a}}\right|^2 + \quad . \quad . \quad . \quad (\alpha)$$

The potential at any external point is

$$A_0\frac{a}{r} + A_1Q_1\left.\overline{\frac{a}{r}}\right|^2 + A_2Q_2\left.\overline{\frac{a}{r}}\right|^3 +, \quad . \quad . \quad . \quad . \quad . \quad (\beta)$$

which may be written $4\pi\frac{a^2}{r}\phi\left(\mu, \frac{a}{r}\right)$.

Similarly we have for the other sphere

$$4\pi b\Phi\left(\mu', \frac{r'}{b}\right) = B_0 + B_1Q_1'\frac{r'}{b} + B_2Q'_2\left.\overline{\frac{r'}{b}}\right|^2 + \quad . \quad . \quad (\gamma)$$

for the potential at any internal, and $4\pi\frac{b^2}{r'}\Phi\left(\mu', \frac{b'}{r'}\right)$ for the potential at any external point.

The whole potential, then, will be given by

$$V = 4\pi\frac{a^2}{r}\phi\left(\mu, \frac{a}{r}\right) + 4\pi\frac{b^2}{r'}\Phi\left(\mu', \frac{b}{r'}\right)$$

at any point external to both spheres.

---

[1] This demonstration was suggested by that given by Thomson (*Reprint of Papers*, p. 10) to establish a slightly different formula.

Also $$V = 4\pi a\phi\left(\mu, \frac{r}{a}\right) + 4\pi\frac{b^2}{r'}\Phi\left(\mu', \frac{b}{r'}\right) \text{ inside } a;$$

and $$V = 4\pi\frac{a^2}{r}\phi\left(\mu, \frac{a}{r}\right) + 4\pi b\Phi\left(\mu', \frac{r'}{b}\right) \text{ inside } b.$$

Now, the conditions of the problem require that the values of V in the two last cases shall be constant. Our functions are, therefore, to be determined by the equations

$$\left.\begin{aligned} a\phi\left(\mu, \frac{r}{a}\right) + \frac{b^2}{r}\Phi\left(\mu', \frac{b}{r'}\right) &= h \\ \frac{a^2}{r}\phi\left(\mu, \frac{a}{r}\right) + b\Phi\left(\mu', \frac{r'}{b}\right) &= g \end{aligned}\right\}, \quad . \quad . \quad . \quad (\delta)$$

which are to be satisfied with obvious restrictions on r and r' in each case. Reverting, however, to the expressions (α), (β), (γ), etc., we see that we need not solve the problem in the general form thus suggested; for it will be sufficient if we determine the constants A_0, A_1, etc., B_0, B_1, etc. Now, if we make $\mu = 1$, $\mu' = 1$, —that is, consider only points on the central line,—then $Q_1 = 1$, $Q_2 = 1$, etc., $Q_1' = 1$, $Q_2' = 1$, etc.[1] A_0, A_1, etc., B_0, B_1, etc., are the coefficients of $\left.\frac{a}{r}\right|$, $\left.\frac{a}{r}\right|^2$, etc., and $\left.\frac{b}{r'}\right|$, $\left.\frac{b}{r'}\right|^2$, etc., in the expressions for the potentials inside the spheres a and b. Hence if $f\left(\frac{r}{a}\right)$ and $F\left(\frac{r'}{b}\right)$ denote the values of $\phi\left(\mu, \frac{r}{a}\right)$, $\Phi\left(\mu', \frac{r'}{b}\right)$, when $\mu = 1$ and $\mu' = 1$, we need only solve the equations

$$\left.\begin{aligned} af\left(\frac{r}{a}\right) + \frac{b^2}{c-r}F\left(\frac{b}{c-r}\right) &= h \\ \frac{a^2}{c-r'}f\left(\frac{a}{c-r'}\right) + bF\left(\frac{r'}{b}\right) &= g \end{aligned}\right\}, \quad . \quad . \quad . \quad (\epsilon)$$

where we have replaced r and r' by their values $c - r'$ and $c - r$, c being the distance between the centres of a and b. Poisson then eliminates the function F, by choosing a new variable ξ, such that $r' = \frac{b^2}{c - \xi}$, and remarks that we may give to ξ any value between $+a$ and $-a$, and therefore we may write r for ξ; we thus have the same variable in both the equations, and $F\left(\frac{b}{c-r}\right)$ which occurs in both may be eliminated. The result is

$$af\left(\frac{r}{a}\right) + \frac{a^2b}{a^2 - b^2 - cr}f\left(\frac{ac - ar}{c^2 - b^2 - cr}\right) = h - \frac{gb}{c - r} \quad . \quad . \quad . \quad (\zeta)$$

This is the functional equation on which depends the solution of the problem of two mutually influencing spheres.

Poisson treats very fully the case of two spheres in contact; for which case, taking $a = 1$, the above equation becomes

$$f(r) - \frac{b}{b + (1+b)(1-r)}f\left(\frac{1 + b - r}{b + (1+b)(1-r)}\right) = h - \frac{gb}{1 + b - r} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\eta)$$

He finds a solution,

$$f(r) = \frac{bh}{(1+b)(1-r)}\int_0^1 \frac{\left(t^{-\frac{1}{1+b}} - 1\right)e^{\frac{br}{(1+b)(1-r)}}}{1-t}dt \quad . \quad . \quad (\theta)$$

It is then easy to find $F(r)$, and write down the general expressions for the potential. Poisson goes on to show that the density at the point of contact of the spheres is zero. He finds, for the mean density on the two spheres 1 and b respectively,

$$A = \frac{bh}{1+b}\int_0^1 \frac{t^{-\frac{1}{1+b}} - 1}{1-t}dt,$$

this being in fact, the value of $f(0)$,

$$\text{and } B = \frac{h}{b(1+b)}\int_0^1 \frac{e^{-\frac{1}{1+b}} - 1}{1-t}dt.$$

He shows that the calculation of the ratio β of A to B may be reduced to the calculation of the first of these integrals only. For the difference $4\pi b^2 B - 4\pi A$ between the charges on 1 and b he finds the elegant expression

$$\frac{4\pi^2 bh}{1+b}\cos\frac{\pi}{1+b},$$

from which it follows that the whole charge is always greater on the sphere of greater radius. He then calculates the value of β for various values of b, and its limit for $b = 0$, and next the ratio of the densities at the two points diametrically opposite the point of contact, and finds for the mean density on each of two equal spheres in contact $A = h \log. 2$. He also calculates for this last case the ratio of the greatest to the mean density. In the case of two unequal spheres, the ratio of the greatest density on the smaller to the mean density on the larger is found for various values of b. He then passes on to investigate the densities for various values of μ.

Plana and Roche.

All these results are compared with the measurements of Coulomb, and found in satisfactory accordance with them. In his first memoir, Poisson considers the case where the distance between the spheres is great compared with the radii; and in a subsequent memoir he considers the case of two spheres at any distance.

Plana (*Sur la distribution de l'électricité à la surface des deux Sphères*, Turin, 1845) extended the calculations of Poisson, using much the same methods. He also calculated approximately the mean densities in the case of several spheres in contact, and arrived at results which agreed satisfactorily with the experiments of Coulomb. For a table of his results, see the end of the first volume of Riess's *Reibungselectricität*. An account of the work of Roche, who also followed in the footsteps of Poisson, will be found in Mascart, t. i., p. 290 *sqq*.

Synthetical method of Green.

The researches of Green led him to a very valuable synthetical method, by means of which we can construct an infinite number of cases where we can find the electrical distribution. Suppose that we take *any distribution whatever* of electricity, for which we know the potential at any point, and consequently the level surfaces. Take any level surface, or parts of level surfaces, inclosing the whole of the electricity, and suppose these level surfaces to become actual conducting sheets of metal. Suppose the electrical distribution inside to be rigid, and connect the sheets of metal with the earth, so as to reduce them to potential zero. The sheets will become charged in such a way that the whole potential at every point in them and external to them is zero. Let now U be the potential at any external point due to inside distribution, and V that due to the charge on the sheets, then we have everywhere on or outside the sheets, $U + V = 0$, or $V = -U$. Now U is constant at every point of each sheet; hence V is so also. Hence the distribution to which V is due is an equilibrium distribution *per se*. Removing now our internal distribution, and changing the sign of that on the sheets, we have a distribution of electricity in equilibrium on a set of conductors of known form, the potential of which at any external point is $V = U$, where U is known. Also the potential V is clearly constant inside every conductor. Hence, applying the characteristic surface equation, we get for the density at any point of any of our conductors the expression

$$\sigma = -\frac{1}{4\pi}\frac{dU}{d\nu}.$$

We might make this a little more general, and state our result thus:—*If we distribute on a level surface or surfaces of any electrical system, completely inclosing that system, electricity with surface density at every point* $\sigma = -\frac{k}{4\pi}\frac{dU}{d\nu}$, *this distribution will of itself be in equilibrium, and the potential at any external point will be* kU.

We have given a physical demonstration of this important theorem. The mathematical reader will easily see the application to this case of the general reasoning about the solution of $\nabla^2 V = 0$, of which we have already given examples. For a simple but interesting case of this general theorem, see Thomson and Tait's *Natural Philosophy*, vol. i., § 508.

Methods of Sir W. Thomson. Electric images.

To Sir William Thomson we owe the elegant and powerful methods of "Electric Images" and "Electric Inversion." By means of these he arrived, by the use of simple geometrical reasoning, at results which before had required the higher analysis. We shall endeavor to illustrate these by two simple examples. We do not follow the methods of the author (for which, see his papers), but take advantage of what we have already laid down.

---

[1] We are, of course, assuming acquaintance with the properties of spherical harmonics.

Let A be any point outside a sphere (fig. 12) of radius a, and centre C. Let $AC = f$, and take B in CA such that $CB \cdot CA = a^2$, or $CB = \frac{a^2}{f}$; then it is easily proved that, if P be any point on the sphere,

$$\frac{BP}{AP} = \frac{a}{f}.$$

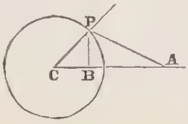

Fig. 12.

Hence if E be any quantity of electricity, we have

$$\frac{E}{AP} - \frac{\frac{a}{f}E}{BP} = 0.$$

Therefore, if we place a quantity E of electricity at A and a quantity $-\frac{a}{f}E$ at B, the sphere will be a level surface of these two, that, namely, for which the potential is zero. Another level surface of the system is evidently an infinitely small sphere surrounding A. Hence it follows, from the theorem of Green which we have just discussed, that a distribution of electricity on the sphere, the density of which is given by $\sigma = \frac{R}{4\pi}$ (where R is the resultant force due to E and $-\frac{a}{f}E$ at any point of the sphere), together with a quantity E at A, gives a system in equilibrium, the potential due to which at any point outside the sphere is the same as that of E at A, and $-\frac{a}{f}E$ at B.

It appears, therefore, that the action of the electricity induced on the uninsulated sphere by the electrified point A is equivalent at all external points to the action of $-\frac{a}{f}E$ at B. The electrified point B is called by Sir William Thomson the electrical image of A in the sphere. It is obvious that the whole charge on the sphere is $-\frac{a}{f}E$, and we can very easily find the density at any point.

In fact, resolving along CP, which we know to be the direction of resultant force, the forces due to A and B, we get

$$R = \frac{E}{AP^2}\cos CPA - \frac{\frac{a}{f}E}{BP^2}\cos CPB$$

$$= \frac{E}{AP^2}\left(\frac{a^2 + AP^2 - f^2}{2aAP}\right) - \frac{fE}{aAP^2}\left(\frac{f^2 + AP^2 - a^2}{2fAP}\right) = -\frac{(f^2 - a^2)E}{aAP^3}.$$

$$\therefore \qquad \sigma = -\frac{(f^2 - a^2)E}{4\pi a AP^3}. \quad . \quad . \quad . \quad . \quad (40)$$

We might have any number of external points and find the image of each. We should thus get a system which might be called the image of the external system. The distribution induced in an uninsulated sphere by such an external system could easily be found by adding up the effect of each external element found by means of its image. Similar methods might also be applied to an internal system. The solution can be generalized without difficulty to the case where either the charge or potential of the sphere is given.

Suppose the charge Q given; superpose on the distribution found above a uniform distribution of amount $Q + \frac{a}{f}E$. This will produce a constant potential $\frac{Q}{a} + \frac{E}{f}$ all over the sphere, and therefore will not disturb the equilibrium. We have thus got the required distribution of the given charge Q under the influence of A. The density of any point is given by

$$\sigma = \frac{Q}{4\pi a^2} + \frac{E}{4\pi af} - \frac{(f^2 - a^2)E}{4\pi a AP}. \quad . \quad . \quad . \quad (41)$$

Electric inversion.

So far the method of images is simply a synthetical method for obtaining distributions on a sphere. But Sir William Thomson has shown us how to convert it into an instrument for transforming any electrical problem into a variety of others.

If P be any point (fig. 13), O a fixed point, and P′ be taken in OP such that $OP \cdot OP' = a^2$, then P′ is called the inverse of P with respect to O, which is called the origin of inversion, or simply the origin; a is the radius of inversion. We may[1] thus invert any locus of points into another locus of points, which we may call the inverse of the former.

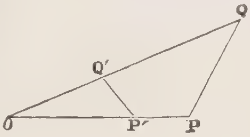

Fig. 13.

Let P, Q and P′, Q′ be any two points and their inverses. Let us suppose that there is a charge E at Q, and a charge E′ at Q′, which is the image of E in a sphere with radius a and centre O; so that $E' = \frac{a}{OQ}E$. Let V and V′ be the respective potentials of E and E′ at P and P′. Then we have obviously

$$\frac{V'}{V} = \frac{a}{r'} = \frac{r}{a},$$

where $OP = r$, $OP' = r'$. It is very easy to show that, if ds, dS, dv, σ, ρ, be elements of length, surface, and volume, and surface and volume densities, and the same symbols with dashes the inverses of these, then we have

$$\left.\begin{array}{l} \frac{ds'}{ds} = \frac{a^2}{r^2} = \frac{r'^2}{a^2}; \ \frac{dS'}{dS} = \frac{a^4}{r^4} \text{ etc.} \\ \text{and } \frac{\sigma'}{\sigma} = \frac{r^3}{a^3} = \frac{a^3}{r'^3}; \ \frac{\rho'}{\rho} = \frac{r^5}{a^5} = \frac{a^5}{r'^5} \\ \text{also } \frac{E'}{E} = \frac{r}{a} = \frac{a}{r'}; \ \frac{V'}{V} = \frac{r}{a} = \frac{a}{r'} \end{array}\right\} . \qquad (42)$$

By means of these equations it is easy to invert any electrical system. Take, for example, the case of any conductor in electrical equilibrium; then, since its potential is everywhere constant, it inverts into a surface distribution, the potential at any point of which distant r' from the origin is by (42) $\frac{a}{r'}C$, where C is the constant potential of the conductor. The surface density at any point of the system is found from that of the corresponding point on the conductor by the equation

$$\sigma' = \frac{a^3}{r'^3}\sigma.$$

Again, if we consider the system thus found, it is obvious that, if we place a quantity $-aC$ of electricity at the origin, this will make the potential at every point of the system zero, and we have a solution of the case of an uninsulated conductor, whose surface is the inverse of that of the given conductor, under the influence of an electrified point.

As an example of the use of this method, let us invert the uniform distribution on a sphere with respect to an origin on its circumference, the radius of inversion being the diameter of the sphere. The sphere inverts into an infinite plane, touching at the other end A of the diameter through the origin. Let C be the potential on the sphere so that $\sigma = \frac{C}{2\pi d}$, where d is the diameter. Hence the density at any point P on an infinite plane influenced by a quantity $-Cd$ of electricity placed at a point O distant d from it is given by

$$\sigma' = \frac{d^2C}{2\pi r'^3}.$$

Again, inverting points inside the sphere, for which the potential is constant, we get the potential due to the distribution on the infinite plane, at points on the other side from the inducing point, the result being

$$V' = \frac{dC}{r'},$$

which is the same as that due to dC at O. Hence the potential at a point on the same side as O is that due to a quantity dC placed at O′, where $O'A = OA$. O′ is in fact the image of O. If we write Q for $-Cd$, then we get

$$\left.\begin{array}{l} \sigma' = \frac{-Qd}{2\pi r'^3} \\ V' = \frac{-Q}{r'} \end{array}\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (43)$$

---

[1] For the general properties of curves and their inverses, the reader may consult Salmon's *Solid Geometry*. He will have no difficulty in proving for himself such as we shall require here.

These results might of course have been deduced as particular cases of a sphere and point.

Many beautiful applications of these methods will be found in the *Reprint* of Sir William Thomson's papers and in Maxwell's *Electricity and Magnetism*. Two of these are of especial importance. Adopting the method of successive influences given by Murphy (*Electricity*, 1833, p. 93), and conjoining with it the method of images, Sir William Thomson treated the problem of two spheres. For his results, see *Reprint*, pp. 86–97. At the end of that paper two valuable tables are given—I. "Showing the quantities of electricity on two equal spherical conductors of radius r, and the mutual force between them, when charged to potentials u and v respectively;" II. "Giving the potentials and force when the charges D and E are given." The ratio of u to v in the first case and of D to E in the second is also given, for which at a given distance there is neither attraction nor repulsion. An interesting experiment on this curious phenomenon is described in Riess, Bd. i. § 186. For an application of di-polar co-ordinates to the problem of two spheres, see Maxwell.

Spherical bowl.

Thomson also applied his methods to determine the distribution on spherical bowls of different apertures. See *Reprint*, p. 178 *sqq*. His numerical results on p. 186 are extremely interesting, as affording a picture of the effect of gradually closing a conductor, and are of great value in giving the experimenter an idea as to what aperture he may allow himself in a vessel which he desires should be for practical purposes electrically closed.

Conjugate functions.

It would lead us too far to discuss here the analytical method of conjugate functions, and the allied geometrical method of inversion in two dimensions. A full account of these, with important applications, will be found in Maxwell, vol. i. § 182 *sqq*.

We shall conclude our applications with a brief notice of a few of the ordinary electro-statical instruments, referring the reader for an account of some others to the article ELECTROMETER.

Parallel plates.

If two plates be placed parallel to each other, and one of them raised to potential V, while the other is connected with the earth, then there will be certain charges E and F on the two plates. If p and r be the coefficients of self-induction for A and B, and q the coefficient of mutual induction, then in the present case

$$E = pV, \qquad F = qV,$$

and the energy of the distribution is obviously

$$Q = \tfrac{1}{2}EV = \tfrac{1}{2}pV^2,$$

so that the work done by completely discharging the condenser $\propto V^2$. If we suppose the plates very large compared with the distance between them, then we may treat the case, for all points not very near the edge, as if the plates were infinite.

In this case the lines of force are straight, and the number of lines of force which leave any area on A is equal to that of those which enter the opposite area on B. Hence the surface densities on the plates are equal and opposite in sign. Also we clearly have

$$\sigma = \frac{R}{4\pi} = \frac{V}{4\pi d}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (44)$$

For the number of lines of force which cross any unit of area parallel to the plates is constant, and therefore the resultant force is constant at every point between the plates.

Principle of accumulators.

It appears, therefore, from (44) that if we make the distance between our plates very small, the density on the inner surface will be very great, and the whole charge on A very great. An apparatus of this kind for collecting large quantities of electricity at a moderate potential is called an accumulator or condenser. One of the first instruments of this kind was Franklin's pane, which consisted of two sheets of tin foil pasted opposite each other on the two sides of a pane of glass. There is of course a practical limit to the increase of capacity in such arrangements, because a spark will pass when the insulating medium is too thin. The greater di-electric strength of glass makes it more convenient than air for an insulating medium, and we shall see by and by that it has other advantages as well. When the plate A is of finite size there will in general be a distribution of electricity on the back comparable with the charge which A would hold at potential V if B were absent. When the distance between the plates is small, by far the greater portion of the capacity is due to the presence of B. Advantage of this principle has been taken in the condensing electroscope of Volta, which is an ordinary gold-leaf apparatus, except that the knob is replaced by a circular disc on which is placed another disc fitted with an insulating handle; the discs are covered with a thin coat of varnish which serves as an insulating medium. If we connect with either disc, say the lower, a source of electricity of feeble potential V, and connect the upper disc at the same time with the earth, then a large quantity of electricity at potential V collects on the lower disc. Now remove all connections, and lift away the upper disc. The capacity of the lower disc is thereby enormously diminished. Therefore, since the charge is unaltered, its potential must rise correspondingly; and the gold leaves may diverge very vigorously, although a simple connection with the lower disc alone would scarcely have moved them. This instrument is of great use in all cases where we have an unlimited supply of electricity at feeble potential. Sir William Thomson has devised an accumulator of measurable capacity, called the Guard Ring Accumulator, which is a modification of the arrangement we are discussing.

Condensing electroscope.

Guard ring accumulator.

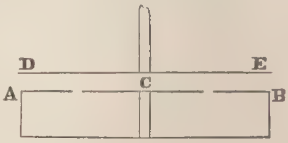

Fig. 14.

AB (fig. 14) is a flat cylindrical metal box, the upper end of which is truly plane, and has a circular aperture, into which fits, without touching, a plane disc C, which is supported on the bottom of the box by insulating supports, so that its upper surface is in the same plane with the lid of the box. DE is a metal disc which can be moved by a screw through measured distances, always remaining parallel to AB. When desired, C can be put in communication with AB. It may then be regarded as forming part of an infinite plate, so that if AB be at potential V, and DE at potential zero, then the surface density on C will be equal to $\frac{V}{4\pi d}$, where d is the distance between the plates; and if A be the area of C the whole amount of electricity on C is $\frac{AV}{4\pi d}$. If now we break the connection between C and the box and discharge the box, we are left with a known quantity of electricity on C, viz. $\frac{AV}{4\pi d}$.

Leyden jar.

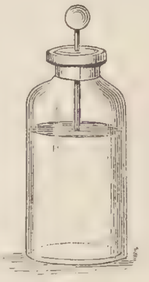

Fig. 15.

The most usual and for many purposes the most convenient form of accumulator is the Leyden jar. This is merely a glass jar (fig. 15) coated to a certain height outside and inside with tinfoil. The mouth of the jar is stopped with a cork or wooden disc, which serves the double purpose of keeping dirt and moisture from the uncovered glass inside, and of carrying a wire in metallic connection with the inside coating, which passes up through the stopper and ends in a metal knob. If the glass of the jar be very thin, we may find the distribution on the two coatings by neglecting the curvature; the electric density on the inner surface of the two coatings will then be the same as in the case of parallel plates. If, therefore, the inner coating be at potential V, and the outer at potential zero, the density on the inner coating will be $\frac{V}{4\pi d}$, and that on the outer $-\frac{V}{4\pi d}$. In the particular case we are considering the inner coating forms very nearly a closed conductor, so that there will be very little electricity on its inner surface, and there will also be very little on the wire and knob compared with the amount on the surface of the inner coating which is next the glass. We may therefore put for the whole electricity on the inner coating $\frac{SV}{4\pi d}$, where S is the extent of its surface. The capacity C of the jar is then given by

$$C = \frac{S}{4\pi d}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (45)$$

Green calculated to a first approximation the effect of the curvature on the capacity, and found that, if R and R′ be the greatest and least radii of curvature of the inner coating at any point, then the densities on the inner and outer coatings are given by

$$\frac{V}{4\pi d}\left\{1 \pm \frac{d}{2}\left(\frac{1}{R}+\frac{1}{R'}\right)\right\}, \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (46)$$

and consequently the capacity of the inner coating by

$$\left\{\frac{1}{4\pi}\iint\frac{dS}{d}+\tfrac{1}{2}\iint\left(\frac{1}{R}+\frac{1}{R'}\right)dS\right\}. \quad \cdot \quad \cdot \quad \cdot \quad (47)$$

Battery of jars abreast.

In any case, C being a constant, we have charge E = CV and energy $Q=\frac{1}{2}CV^2$. Hence if we connect the inner coatings of n similar jars, and charge them to potential V, all the outer coatings being at the same time connected with the earth, we have E and Q representing the whole charge and energy,

$$\left.\begin{aligned} E &= nCV \\ Q &= \frac{n}{2}CV^2 \end{aligned}\right\} \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (48)$$

If we discharge such a battery of n jars into another of n' similar jars, by connecting the knobs together, and the outer coatings to earth in each case, we have, U being the common potential after discharge,

$$nCV = nCU + n'CU$$

$$\text{and } U = \frac{n}{1+n'}V. \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (49)$$

There is therefore a loss of energy represented by

$$\tfrac{1}{2}nCV^2 - \tfrac{1}{2}(n+n')CU^2,$$

that is

$$\frac{nn'}{2(n+n')}CV^2. \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (50)$$

In other words, an $\frac{n'}{n+n'}$th part of the potential energy is lost. When a battery of jars is discharged through a circuit in which there is a fine wire of large resistance, the greater part of the potential energy lost in the discharge appears as heat in the fine wire. Riess made elaborate experiments on the heating of wires by the discharge in this way, and the results of his experiments are in agreement with the formulæ which we have just given. (See Heating Effects.)

Battery in series.

We may also arrange a battery of jars by first charging each separately to potential V in the usual way, and then connecting them in series, so that the outer coating of each jar is in metallic connection with the inner coating of the next. In such an arrangement of jars, it is obvious that in passing from the outer coating of the last at potential zero to the inner coating of the first, the potential will rise to nV. When we come to discharge such a series, the electro-motive force to begin with is nV, so that for any purpose in which great initial electro-motive force is required this combination has great advantages over n jars abreast. The "striking distance," for instance, *i.e.*, the greatest distance at which the discharge by spark will just take place through air, is much greater. On the other hand the quantity of electricity which passes is less, being only CV instead of nCV; the whole loss of potential energy in a complete discharge is, however, the same.

Cascade.

The case which we have been discussing must be carefully distinguished from that of a series of jars charged by "cascade," where n uncharged jars are connected up in succession as in last case, and the first charged by connection with the electric machine to potential V, while the outer coating of the last of the series is connected to earth, and the rest of the jars insulated. The whole electro-motive force in this case is clearly only V, and, if all the jars be similar, the potential difference between the coatings in each is $\frac{V}{n}$; the charge on the inner coating of the first is therefore $\frac{CV}{n}$, and the whole potential energy only $\frac{1}{2}\frac{CV^2}{n}$. The arrangement is, therefore, not so good as a single jar fully charged by the same machine. It was fancied by Franklin, who invented this method of charging, that some advantage was gained by it in the time of charging, the notion being that the overflow was caught by the successive jars and that electricity was thereby saved. Charging by cascade was treated by Green. Some of the experiments of Riess bear on the matter (*vide* Mascart, §§ 190, 191), which, after all, is simple enough.

Free and bound electricity.

In the theory of accumulators, or condensers as they are often called, much stress has been laid on the difference between "*free*" and "*bound*" electricity. To illustrate the meaning of these terms, let us take a case where the calculations can be carried out in detail.

Suppose we have two concentric spherical shells, an inner, A, and an outer, B. Let the outer radius of A be a, and the inner and outer radii of B be b and c, so that the thickness of the latter is $c-b$. We shall suppose that we can, when we please, connect the inside sphere with the earth. It is clear that there can never be any electricity on the inner surface of A. Let the charges on the other surfaces in order be E, F, G. Let us suppose in the first instance that A is at potential V, and B at zero. Then we have to find E, F, G. Draw a surface in the substance of B; no lines of force cross it, therefore the whole amount of electricity within is zero. Hence F = − E. Also, considering the external space, which is inclosed between two surfaces of zero potential, we see that G = 0. Thus, since A is at potential V, we have $\frac{E}{a}-\frac{E}{b}=V$.

$$E=\frac{ab}{b-a}V=pV\left(\text{where } p=\frac{ab}{b-a}\right). \quad \cdot \quad \cdot \quad \cdot \quad (51)$$

In this case, then, there is no electrification on the outside of B, and an electric pendulum suspended there would give no indication. Let us now connect A with the earth, so that its potential becomes zero; we have now to find the charges and potentials, our datum being that the whole charge on B is − E.

As before, we have F′ = − E′, but G is no longer zero. We have, however, F′ + G′ = − E. Hence G′ − E′ = − E.

Also, since A is at zero potential, $\frac{E'}{a}-\frac{E'}{b}+\frac{G'}{c}=0$,

therefore $G'=\frac{-cE'}{p}$; $-F'=E'=\frac{pE}{p+c}$; $G'=\frac{-cE}{p+c}$.

The potential of B is $\frac{G'}{c}$, or $\frac{-cpV}{p+c}$.

In this process, therefore, a quantity E − E′, or $\frac{cp}{p+c}V$, of electricity has flowed away to earth from A, and a quantity $\frac{-cp}{p+c}V$ has passed from the inner to the outer surface of B, while the potential has altered on A from V to 0, and on B from 0 to $\frac{-cp}{p+c}V$.

Suppose now we connect B with the earth, thus reducing it to zero potential. Since the charge on A remains the same, and that on the inner coating of B is equal and opposite to it, it follows that now the charges on A, etc., are $\frac{pq}{c}V$, $\frac{-pq}{c}V$, 0, where q denotes $\frac{cp}{p+c}$; and the potentials of A and B are $\frac{q}{c}V$ and 0. After another pair of such operations the charges will be $\frac{pq}{c}\frac{q}{c}V$, etc., and the potential, $\left.\frac{q}{c}\right|^2 V$; after a third, charges, $\frac{pq}{c}\left.\frac{q}{c}\right|^2 V$, etc., and potential, $\left.\frac{q}{c}\right|^3 V$. Hence the charges and potentials go on decreasing in geometrical progression. Amounts of electricity flow away from A equal to qV, $q\frac{q}{c}V$, $q\left.\frac{q}{c}\right|^2 V$, $q\left.\frac{q}{c}\right|^3 V$, etc., in the successive operations, and equal amounts of opposite signs are discharged from B. The sum of all these discharges is the whole original charge on A, for

$$qV\left(1+\frac{q}{c}+\left.\frac{q}{c}\right|^2+\text{etc., } ad.\ inf.\right)=\frac{q}{1-\frac{q}{c}}V=pV.$$

Hence by an infinite number of alternate connections we shall finally discharge the jar completely. The electricity which flows out at each contact is called the "free electricity," and that which remains behind the "bound electricity." The quantity which we have denoted by p is clearly the capacity of a spherical Leyden jar; it increases indefinitely as the distance between the conducting surfaces decreases, and is very nearly proportional to the surface of the inside coating, when the distance is small compared with the radius of either surface.

Capacity of spherical jar.

It is very easy to extend our reasoning to any condenser. If, in fact, q_{11}, q_{12}, q_{22} be the coefficients of self and mutual induction for the armatures, then this potential after operating n times as above is $\left(\frac{q_{12}^2}{q_{11}\,q_{22}}\right)^n$V, the charges, $q_{11}\left(\frac{q_{12}^2}{q_{11}\,q_{22}}\right)^n$V and $q_{12}\left(\frac{q_{12}^2}{q_{11}\,q_{22}}\right)^n$V, and the amounts of electricity which leave 1 and 2 in the nth operation are $\pm qq_{11}\left(\frac{q_{11}\,q_{22}-q_{12}^2}{q_{11}\,q_{22}}\right)\left(\frac{q_{12}^2}{q_{11}\,q_{22}}\right)^n$V respectively.

Coaxial cylinders.

We must not omit one more interesting case. If we have two infinite coaxial cylinders of radii a and b ($b > a$), then obviously the potential is symmetrical about the common axis, and Laplace's equation becomes

$$\frac{d^2V}{dr^2}+\frac{1}{r}\frac{dV}{dr}=0\,.$$

The integral of this is $V = C \log r + D$. Let the inner cylinder be at potential V_1, the outer at potential V_2, then

$$V=(V_1-V_2)\,\frac{\log r}{\log a-\log b}+\frac{V_2\log a-V_1\log b}{\log a-\log b}\,. \qquad (52)$$

Hence the surface density on the inner cylinder is given by

$$\sigma=-\frac{1}{4\pi}\frac{dV}{dr}=\frac{V_1-V_2}{4\pi a\log\frac{b}{a}}\,;$$

and the capacity per unit of length of same is

$$\frac{1}{2a\log\frac{b}{a}}\,. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (53)$$

This result has important applications in the theory of telegraph cables, and to a form of graduated accumulator, invented by Sir William Thomson, and used by Messrs. Gibson and Barclay in their experiments on the specific inductive capacity of paraffin (see Maxwell, vol. i. § 127).

ON THE INSULATING MEDIUM.

It has been assumed hitherto that the medium interposed between the conductors in the electric field is in all cases air—the most prevalent of all di-electric media; or, where any other medium actually occurred, as in the case of the Leyden jar, it has been assumed that the result is the same as if the glass were replaced by air. Experimenters soon recognized, however, that the capacity of a Leyden jar depends very much on the quality of the glass of which it is made. But the nature of this action was very little understood, until Faraday showed by a number of striking experiments that the di-electric has a specific function in all phenomena of induction.

Faraday's experiments.

Faraday used in his experiments two identical pieces of apparatus, which were virtually two spherical Leyden jars. The outer coating EF (fig. 16) was divided into two hemispheres, which could be fitted together air-tight. The lower hemisphere F was fitted to a perforated stem, provided with a stopcock G, so that it could be screwed to an air-pump while the apparatus was being exhausted, and afterwards screwed into a foot H. The upper hemisphere was pierced by a tube, into which was cemented a shellac plug B. C is a metal wire passing down through B, which supports the hollow metal sphere D, forming the inside armature, and carries the metal ball A, by means of which D can be charged and discharged. To give an idea of the size of the apparatus, it may be mentioned that the diameters of the inner and outer spheres were 2·33 in. and 3·57 in. respectively. Two jars were made on the above pattern, as nearly alike as possible. The equality of their capacities was tested as follows. Both were filled with air at the same temperature and pressure. Apparatus I. was then charged, by bringing A in communication with the knob of a Leyden jar, while the coating EF was connected to earth. I. and II. were then placed at a moderate distance from each other, as symmetrically as possible with respect to the observer and other external objects, the outer armatures in both cases being in conducting communication with the earth. The ball of I. was touched by a small proof sphere, the repulsion of which on the movable ball of a Coulomb balance was measured; after a short interval this measurement was repeated. The balls of I. and II. were then brought into communication, and the charge divided between the internal armatures. The ball of II. was immediately tested as before, and then the ball of I. again. Finally I. and II. were discharged and tested for permanent "stem effect." The result of one such series of measurements was

I.	 254,250	 124	1 . . .
II.	0, ...	122	. . . 2

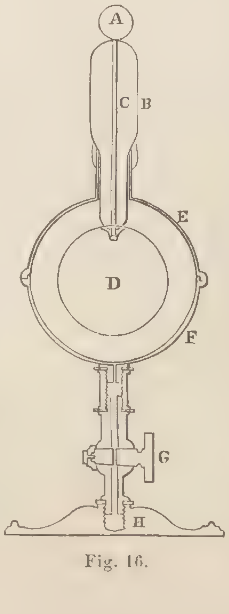

Fig. 16.

Neglecting the slight dissipation of the charge, and taking account only of the "stem effect" in I., we see that the charges on I. and II. after division are represented by 122 and 124, each of which is not far from the half of the whole disposable charge in I., viz., 124·5; so that the capacities of the two jars must be equal. This will perhaps be clearer if we consider what would happen were the capacities unequal. Let the capacities be C and C′, the potential of I. before division V, and the common potential after U, the charge on I. Q, and on I. and II. q and q' after division. Then $Q = CV$, $q = CU$, $q' = C'U$, and $q + q' = Q$. The indication of the torsion balance is proportional to the charge of the proof sphere, that is (owing to the symmetry of the arrangements), to the potential of the knob with which it was in contact; or at all events this is true if we consider only readings taken from the knob of the *same* jar, and that is all we shall ultimately want. But $(C + C')\,U = CV$; hence

$$\frac{C'}{C}=\frac{V-U}{U}\,.$$

Hence the ratio of the capacities is equal to the ratio of the excess of the first over the last reading to the last reading, both being taken from the knob of I. Thus, taking the uncorrected values in the above experiment, the ratio of the capacities would be (250 − 124) ÷ 122, *i.e.* 1·02. By various experiments of this kind, Faraday convinced himself of the equality of his two jars. To test the sensibility of his method, he reduced the distance between the lower hemispheres and the ball in II. from ·62 in. to ·435 in., by introducing a metal lining. The capacity of II. was then found to be 1·09 (the mean of two observations). He next compared the capacities of the jars when the lower half of the space between the armatures of one of them was filled with shellac. The ratio of the capacities was found to be 1·5 (mean of several experiments), the shellac jar having the greater capacity.

Specific inductive capacity.

It appears, therefore, that, other things being equal, the capacity of an accumulator is greater when the insulating medium, or, as it is called, the "di-electric," is shellac, than when it is air. The ratio of the capacity in the former case to that in the latter[1] is called the *Specific Inductive Capacity* of shellac. This we shall in general denote by K. According to this definition, air is taken as the standard, and its specific inductive capacity is unity. Properly speaking, we ought to state the temperature and pressure of the air; we may assume 0° C. as our temperature, and the average atmospheric pressure (760 mm.) as our standard barometric pressure.

It is easy to obtain an approximate value of K from the above result for the shellac apparatus. Remembering that the shellac occupies only one hemisphere, and assuming that the lines of force are not disturbed at the junction of the air and shellac, we have, if ρ denote the ratio of the capacities,

$$\frac{1+K}{1+1}=\rho, \text{ and } K=2\rho-1.$$

This gives for shellac K = 2·0, the real value being probably greater. Similar experiments gave for glass and sulphur K = 1·76 and 2·24 respectively.

Thus the specific inductive capacities of shellac, glass, and sulphur are considerably larger than that of air. Faraday was unable to find any difference in this respect between the different gases, or in the same gas at different temperatures and pressures, although he made careful experiments in search of such differences.

It would lead us too far to discuss in detail the precautions taken by Faraday to remove uncertainty from his experimental demonstration of the existence of a specific di-electric action. The reader will find a minute description in Faraday's own surpassingly lucid manner in the eleventh series of the *Experimental Researches.*

---

[1] It must be noticed that the assumption is tacitly made that the air is to be replaced by shellac *everywhere*, or at least wherever there are lines of force.

Faraday's theory.

His discovery of the action of the medium led Faraday to invent his well-known theory of the di-electric. According to him, the fundamental process in all electrical action is a polarization of the ultimate particles of matter; this polarization consists in the separation of the positive and negative electricities *within* the molecules, exactly as the two magnetic fluids are supposed to separate in the theory of magnetic induction. In this view a di-electric is supposed to consist of a number of perfectly conducting particles, immersed in a medium or menstruum, which is either a non-conductor or a very imperfect conductor. When electrical action starts, the two electricities separate in the molecules; but in the first instance at least there is no interchange of electricity between different molecules. Faraday assumed that the electrical action is propagated from molecule to molecule by actions whose sphere of immediate activity is very small. He denied the existence of "action at a distance," and regarded his results about induction in curved lines as at variance with it. Thomson[1] showed, however, that Faraday's results were perfectly consistent with the theory of action at a distance, provided the polarization of the di-electric be taken into account, and that the mathematical treatment of the subject is identical with Poisson's theory of induced magnetism. The theory of action at a distance as applied to this subject will be found under MAGNETISM. Helmholtz, whose memoirs we have already mentioned, takes this view of the matter. We do not propose to follow Faraday's theory any further at present; its main features are involved in Maxwell's theory, to which we shall afterwards allude.

Siemens.

W. Siemens[2] examined and confirmed the conclusions of Faraday. He used voltaic electricity in comparing the capacities of condensers. By means of a kind of self-acting commutator[3] (*Selbstthätige Wippe*), the armatures of the condenser were connected alternately with a battery of Daniell's cells and with each other; so that the condenser was charged and discharged about 60 times per second.

Figure 17 gives a scheme of the arrangement. F and G are two insulated metal screws, with which the vibrating tongue E of the Wippe comes alternately into contact; CD and AB are the armatures of the condenser, H the battery, and K the galvanometer. Theory indicates, and experiment confirms, that the deflection will be the same whether the galvanometer is put in the charge or in the discharge circuit. The former arrangement is that indicated in the figure.

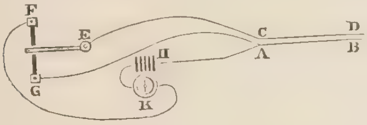

Fig. 17.

The amount of electricity which flows through the galvanometer each time the condenser is charged, is proportional to the product of the capacity C of the condenser and the electro-motive force E of the battery. E is proportional to the number of cells in the battery. If, therefore, the speed of the Wippe be constant, the galvanometer deflection, or its sine or tangent as the case may be, will be proportional to EC. By varying E and C independently, we can verify the laws that regulate the charge of condensers. If we keep E the same, and the speed the same, we can compare the capacities of two condensers, or of the same condenser with two different di-electrics, and thus find the specific inductive capacities of various substances with respect to air. Siemens found that C is independent of E, and concluded that the effect of solid di-electrics on the capacity of a condenser is not to be explained by a penetration of the electricity into the di-electrics. We shall give some of his values of the specific inductive capacity farther on.

Gaugain.

Gaugain[4] studied the effect of the insulator on the capacity of condensers. He used in his researches the discharging electroscope (see art. ELECTROMETER), an instrument which does not at first sight look likely to lead to very accurate results, but which seems to have worked satisfactorily in his hands. Many of Gaugain's results concerning the gradual increase of the charge are very interesting; their bearing on theory is difficult to estimate, however, owing to the mixture of effects due to surface and body conduction. His results concerning the "limiting" value of the specific inductive capacity are at variance with those of subsequent experimenters who have worked with more delicate instruments.

Gibson and Barclay. Platymeter.

In their experiments on the specific inductive capacity of paraffin, Gibson and Barclay[5] employed a method due to Sir William Thomson, in which an instrument called the Platymeter is used in conjunction with the quadrant electrometer. They found for the specific inductive capacity of paraffin 1·97, and showed that this value alters very little, if at all, with the temperature.

Boltzmann.

The most extensive measurements of this kind that have been made of late are those of Boltzmann[6] and Schiller.[7] Boltzmann used a sliding condenser, whose plates could be placed at measured distances apart. Plates of different insulating materials were introduced between the parallel plates of the condenser, so as to be parallel with them and at different distances from one of them.

According to the mathematical theory, the capacity of the condenser is independent of the position of the plate, and varies inversely as $m - n + \frac{n}{K}$, where m is the distance between the plates of the condenser, and n the thickness of the plate of insulating material whose specific inductive capacity is K. In other words, the plate may be supposed replaced by a plate of air of thickness $\frac{n}{K}$. If therefore λ denote in absolute measure the reciprocal of the capacity of the condenser, then

$$\lambda = G\left(m - n + \frac{n}{K}\right),$$[8]

where G is a constant. The capacity of the condenser was measured by charging it with a battery of 6 to 18 Daniell's cells, and then dividing its charge with the electrometer. One pole of the battery and one armature of the condenser are connected to earth. The other pole of the battery is first connected with the electrode A of the electrometer, whose other electrode B is connected to earth. Let the reading thus obtained be E, then E is proportional to the potential of the battery pole. The condenser is next charged by connecting its insulated armature with the battery; the battery connection is then removed, and the electrode A of the electrometer, which has meanwhile been connected with the earth, is now connected with the condenser. If C be the capacity of the condenser, C′ that of the electrometer (in certain cases artificially increased), we have, if F be the common potential of the condenser and connected parts of the electrometer, $(C+C')F = CE$, and

$$C = \frac{FC'}{E-F}, \qquad \text{or} \qquad \lambda = \frac{E-F}{F} \cdot \frac{1}{C'}.$$

But F is proportional to the second reading of the electrometer, hence λ is known in terms of C′. As only relative measures are wanted, C′ is not required. Boltzmann made a variety of experiments, all of which confirmed the theory, and showed the applicability of the above formula.

If we make three measurements, first with the plates at distance m_1; secondly, at distance m_2, with only air between in each case; and thirdly, at distance m_3, with an insulating plate of thickness n between, we have, if λ_1, λ_2, λ_3 be the corresponding values of λ,

$$G \quad \frac{\lambda_2 - \lambda_1}{m_2 - m_1}, \quad \text{and} \quad \frac{1}{K} = \left(\frac{\lambda_3 - \lambda_1}{G} - m_3 + m_1 + n\right) \div n.$$

The advantage of this procedure is that only differences of m_1, m_2, m_3 come in, and no absolute length has to be measured. Measurements were also made with condensers, in which there was no air between the armatures and the insulating plates; in them the armatures were formed by means of mercury. To give an idea of the agreement of the results by different methods, we give K for paraffin as determined on plates of different thickness; with the ordinary condenser, K = 2·28, 2·34, 2·31 for plates I., II., and III.; and K = 2·31, 2·33 for plates I. and II. used with mercury armatures.

[8] It is supposed that the plates are near enough to allow us to neglect the effect of the rims.

Effect of time.

Boltzmann convinced himself that, in the case of ebonite, paraffin, sulphur, and rosin, the time during which the condenser was charged was without sensible influence. He found that the result was the same whether the charge was instantaneous or lasted for a considerable time. The case was different with the imperfect insulators, glass, stearine, and gutta percha, for which he has given no results. To test still further the influence of the time, Boltzmann measured the attraction between a sulphur and a metal sphere—first, when the latter was charged continuously positive or negative, and, secondly, when it was charged positive for $\frac{1}{200}$th of a second, negative for the next $\frac{1}{200}$th, and so on; he found the attraction to be the same in both cases, provided the charges without respect to sign were equal. This experiment establishes beyond a doubt the existence, in the case of sulphur, of a specific di-electric action, which is fully developed in less than $\frac{1}{200}$th of a second. From experiments of this kind values of K were deduced, which agreed fairly well with those obtained by other methods. A very important result which he obtained was, that for a certain crystalline sphere of sulphur the values of K were different in the directions of the axes, being 4·773, 3·970, and 3·811 respectively. The result realizes an expectation of Faraday.[1]

Schiller. Method of electrical oscillations.

Schiller employed two methods—the method of Siemens, which we have already described, in which the duration of charge was from $\frac{1}{40}$th to $\frac{1}{50}$th of a second, and the method of electrical oscillations devised by Helmholtz. In the latter method K is given by the equation $K = (T^2 - T_0^2) \div (T'^2 - T_0^2)$, where T_0, T, T', are the periods of oscillation of a certain coil, firstly, by itself, secondly, when connected with an air-condenser, and thirdly, with the same condenser when the air is replaced by the insulator to be tested (see below, p. 77). In this method the duration of charge varied from $\frac{1}{20000}$th to $\frac{1}{5000}$th of a second.

The following table gives some of the results of Boltzmann and Schiller:—

	Boltzmann.	Schiller.	
Ebonite	3·15	2·76	2·21
Paraffin (clear)	2·32	1·92	1·68
Do. (milky)		2·47	1·81
Sulphur	3·84	......	......
Rosin	2·55	......	......
India-rubber (pure)	......	2·34	2·12
Do. (vulcanized)	......	2·94	2·69
White mirror glass	......	6·34	5·88

The first column of Schiller's results was obtained by Siemens's method, the second by the method of oscillations. It will be seen that the shortness of the time of charge has affected the value of K in the last column, reducing it considerably in all cases. Boltzmann's results are on the whole the largest obtained by any physicist; he attributes this to the care with which he constructed his plates. Gibson and Barclay found 1·97 for paraffin, and Siemens 2·9 for sulphur.

Among the more recent researches on the theory of di-electrics may be mentioned those of Rood,[2] whose results for crystals are interesting, and Wüllner,[3] who has studied the course of induction when the charge is maintained for a considerable time.

Silow. Results for fluids.

There are very few fluids which are sufficiently good insulators to allow an easy determination of their specific inductive capacity. Measurements have, however, been made by Silow.[4] He used (1) Siemens's method, and (2) a method in which he observed the deflection of a quadrant electrometer corresponding to the same potential, first, when the quadrants were filled with air, and secondly, when they were filled with the fluid to be examined; the ratio of the latter deflection to the former is the specific inductive capacity of the liquid.

The instrument actually used was a glass vessel, inside which were pasted pieces of tinfoil corresponding to the quadrants of Thomson's electrometer. The shape of the needle was also slightly different. A fine silver wire replaced the bifilar suspension, and the deflections were read off by means of a scale and telescope. The needle and one pair of quadrants were connected with the earth, and the other pair of quadrants charged to a constant potential by connection with a battery. The results were for oil of turpentine by method (1), 1·468; by (2), 1·473; for a certain specimen of petroleum, by (1), 1·439; for another specimen, by (2), 1·428; for benzol, by (1), 1·483.

In the researches in which Siemens's method was used, the speed of the commutator was varied considerably, but no effect was thereby produced on the value of K, which is, therefore, within certain limits at least, independent of the duration of the charge.

Gases. Boltzmann.

Perhaps the most important of all the recent additions to our knowledge in this department is due to Boltzmann,[5] who has succeeded in detecting and measuring the decrease of the specific inductive capacity of gases when rarified.

The principle of his method is as follows. Suppose we have an ordinary air-condenser inside a receiver, which we can exhaust at will. Let one of the armatures A of the condenser be connected with a battery of a large number n of cells (Boltzmann used about 300 Daniell's), while the other armature B is connected with the earth. If we now insulate B, and if the condenser does not leak, then on connecting B with the electrometer no deflection will be indicated. If, however, we increase the number of cells by one, the potential of A will increase from np to $(n+1)p$, while that of B will rise from 0 to an amount which is proportional to p. Let the corresponding electrometer reading be β. Suppose now that we altered the specific inductive capacity of the gas from K_1 to K_2, both armatures being insulated, A originally at potential np, and B at potential zero; the potential of A will, by the mathematical theory, become $\frac{K_1}{K_2} np$, while that of B remains zero. If now we reconnect A with the battery of n cells, the potential of A becomes again np. If we then connect B with the electrometer we shall get a deflection α proportional to

$$np\left(1 - \frac{K_1}{K_2}\right); \text{ hence we have } \frac{-\alpha}{\beta} = n\left(1 - \frac{K_1}{K_2}\right).$$

Let us now assume, what experiment shows to be the case, that the increase of K is very nearly proportional to the pressure, then, b_1 and b_2 denoting the manometric reading in millimetres corresponding to K_1 and K_2, we may write

$$K_1 = c\left(1 + \frac{\lambda b_1}{760}\right), \quad K_2 = c\left(1 + \frac{\lambda b_2}{760}\right).$$

Here λ is a constant, the meaning of which is very simple, if we assume our law of proportionality to hold up to absolute vacuum; in fact, $1 + \lambda$ is in that case the specific inductive capacity[6] of the gas at 760 mm. pressure, at the temperature t of observation, and $1 + \lambda(1 + \alpha t)$ is the corresponding coefficient at 0° C. The formula written above becomes therefore

$$\lambda = \frac{\alpha . 760}{\beta n(b_1 - b_2)}.$$

In this way Boltzmann arrived at the following values for $\sqrt{K}$ at 760 mm. pressure, and temperature 0° C.;—for air, 1·000295; carbonic acid, 1·000473; hydrogen, 1.000132; carbonic oxide, 1.000345; nitrous oxide, 1·000497; olefiant gas, 1·000656; marsh gas, 1·000472. These results are of great importance in connection with the electro-magnetic theory of light.

Residual Discharge.

Phenomena of latent charge.

When an accumulator, whose di-electric is glass or shellac, is charged up to a moderately high potential, and one armature insulated, a gradual fall of the potential occurs. This fall is tolerably rapid at first, but it gets slower and slower till at last it reaches a certain limit, after which it remains sensibly constant for a considerable time. This fall is not entirely due to loss by conduction or convection of the ordinary kind, for we find that if an accumulator that has been charged to potential V, and has been allowed to stand till the potential has fallen considerably, be again charged up to potential V, then the rate of loss is much less than before, being now very nearly constant, and not far from the limit above mentioned. It would appear, therefore, that this constant limit, which on favorable days is very small, represents the loss due to convection and conduction in the usual way, and that the larger varying loss is due to some other cause. When an accumulator, let us say a Leyden jar, has been repeatedly charged up to potential V, until the rate of dissipation has become constant, we shall say that it is saturated. If we discharge a saturated jar, by connecting the knob for a fraction of a second with a good earth communication, and then insulate the knob, the outer coating being supposed throughout in connection with the earth, we find that the instant after the discharge the potential of the knob is zero; after a little, however, it begins to rise, and by and by it reaches a value which is a considerable fraction of V, and has the same sign. This phenomenon justifies the assumption we made as to the peculiar nature of the variable loss of potential experienced by a freshly charged jar. The charge which reappears in this way subsequent to the instantaneous discharge is called the residual discharge.[1] If at any time during the appearance of the residual charge the jar be discharged, the potential of the knob becomes for a short time zero, but begins to rise again; and this may be repeated many times before all trace of charge disappears. Faraday made a variety of experiments on the subject, and established that whenever a charge of positive electricity disappeared or became latent in this way, an equal negative charge disappeared in a similar way. He concluded that the cause of the phenomenon was an actual penetration of the two electricities (*Exp. Res.*, 1245) by *conduction* into the di-electric. This is not the view which is favored by the best authorities of the present day; it is indeed (see Maxwell, *Elect. and Mag.*, vol. i. § 325) at variance with the received theories of conduction, and alike untenable, as far as we know, whether we adopt the theories of Weber, of Maxwell, or of Helmholtz. Faraday established that time was a necessary condition for the development of the phenomenon; and he was thus enabled to eliminate its influence in the experiments on the specific inductive capacity of sulphur, glass, and shellac. The phenomenon is most marked in the last of these; and in spermaceti, which relatively to these is a tolerably good conductor, the phenomenon is very marked, and develops very rapidly.

[6] K is now taken to be = 1 for absolute vacuum.

Investigations of Kohlrausch.

Kohlrausch[2] studied the residual discharge in an ordinary Leyden jar, in a jar whose outside and inside coatings were at one time quicksilver and at another acidulated water, and in a Franklin's pane, one side of which was coated with tinfoil in the usual way, while the other was silvered like a piece of looking-glass. He showed, by taking measurements with an electrometer and a galvanometer, *that the ratio of the free or disposable charge to the potential is constant.* By the disposable charge is meant the charge which is instantaneously discharged when the knob of the jar is connected with the earth. This ratio is the capacity of the jar, and it appears that it is independent of the "residual" or "latent" charge. He showed that the "latent" charge is not formed by a temporary recession of the electricity to the uncovered glass about the neck and upper part of the jar; and that it does not to any great extent depend on the material used to fasten the armature to the glass, or on the air or other foreign matter between them. On the other hand, his results led him to suspect that the "latent" charge depended on the thickness of the glass, being greater for thick plates than for thin. This conclusion has been questioned, however.[3] He separated by a graphical method the loss by latent charge from the loss by conduction, etc., and found *that the amount of charge which becomes latent, or, which amounts to the same thing, the loss of potential owing to the forming of latent charge in a given time, is proportional to the initial potential so long as we operate with the same jar.*

His theory.

Kohlrausch recognized the insufficiency of Faraday's explanation of the residual charge, and sought to account for it by extending Faraday's own theory of the polarization of the di-electric. The residual charge is due according to him to a residual polarization of the molecules of the di-electric, which sets in after the instantaneous polarization is complete, and which requires *time* for its development. This polarization may consist in a separation of electricity in the molecules of the di-electric, or in a setting towards a common direction of the axes of a number of previously polarized molecules, analogous to that which Weber assumes in his theory of induced magnetism. It is easy to see that such a theory will to a great extent account for the gradual reduction of the potential of a freshly charged jar, and the gradual reappearance of the residual charge.

If the charge, and consequently the potential, of the jar were kept constant at Q_0, the residual charge tends to a limit pQ_0 (p const.). Kohlrausch assumes that the difference $r_t - pQ_0$ between the residual charge actually formed and the limit decreases at a rate which is at each instant proportional to this difference, and furthermore, to a function of the time, which he assumes to be a simple power. In any actual case, where the jar is charged and then insulated, the charge varies, owing to conduction, etc., and to the formation of residual charge, so that the limit of r_t is continually varying, and we must write Q_t for Q_0, Q_t denoting the charge at time t. The equation for residual charge is then

$$\frac{d}{dt}(r_t - pQ_t) = -bt^m(pQ_t - r_t).$$

From this he deduces the formula

$$rt = p\left(Qt - Q_0 e^{-\frac{b}{m+1}t^{m+1}}\right),$$

which he finds to represent his results very closely. m has very nearly the same value ($-0{\cdot}5744$, or $-\frac{1}{2}$ nearly) in all his experiments, p had the values 0·4289, 0·5794, 0·2562; and b, 0·0397, 0·0223, 0·0446 in his three cases.

Analogous phenomena.

Kohlrausch called attention to the close analogy between the residual discharge and the "elastic recovery" (*elastische Nachwirkung*) of strained bodies, which had been investigated by Weber[4] in the case of a silk fibre, and which has of late excited much attention. The instantaneous strain which follows the application of a stress is analogous to the initial charge of the jar, and the gradually increasing strain which follows to the gradual formation of the latent or residual charge. The sudden return to a position near that of unconstrained equilibrium corresponds to the instantaneous discharge, and the slow creeping back to the original state of equilibrium to the slow appearance of the residual discharge. Another analogy may be found in the temporary and residual or subpermanent magnetism of soft iron or steel. If we wish to make the analogy still more complete, we have only to introduce the permanent polarity of tourmaline, the permanent set of certain solids when strained, and the permanent magnetism of hard steel. The phenomena of polarization furnish yet another analogy.

Effect of duration of charge.

In justifying the introduction of a power of the time into his equation for the residual discharge, Kohlrausch makes the important remark that the time which a residual charge of given amount takes to reappear fully may be different according to the way that charge is produced. The charge reappears more quickly when it is produced in a short time by an initial charge of high potential, than when produced by a charge of lower potential acting longer. He suggests that the same thing may be true of elastic recovery. He does not allude to the fact (possibly he was unaware of it) that two residual charges of different sign may be superposed and reappear separately, although the possibility of this is to a certain extent involved in his remark. The analogous elastic phenomenon has recently been observed by F. Kohlrausch.

Maxwell's theory.

Maxwell[5] has shown that phenomena exactly like the residual discharge would be caused by *conduction in a heterogeneous* di-electric, each constituent of which by itself has not the power of producing any such phenomenon, so that the phenomenon in general might be due to "heterogeneity" simply.

Hopkinson's experiments.

Hopkinson has lately made experiments on the residual discharge of glass jars. He observed the superposition of residual charges of opposite signs, and he suggests theories analogous to those of Kohlrausch and Maxwell. He finds that his results cannot be represented by the sum of two simple exponential functions of the time, and concludes, therefore, that heterogeneity must be an important factor in the cause of the phenomenon.

The polarities of the different silicates of which the glass is composed rise or decay with the time at different rates, so tha during insulation the difference of potential between the armatures E would be represented by a series $\Sigma_0^n A_r e^{-\lambda_r t}$. If, therefore, we charge a jar positively for a long time, and then negatively for a shorter time, the second charge will reverse the more rapidly changing polarities, while the sign of the more sluggish will not be changed; when, therefore, the jar is discharged and insulated, the first-mentioned polarities will decay more quickly at first and liberate a negative charge, and finally, as the more sluggish also die away, a positive charge will be set free. Hopkinson also made the important observation that agitation of the glass by tapping accelerates the return of the residual discharge.

---

[1] When we think of the part of the charge that has disappeared, *i. e.*, ceased to effect the potential of the knob, we may talk of the "latent charge." This part of the charge is sometimes said to be absorbed.

ON THE PASSAGE OF ELECTRICITY THROUGH BODIES.

Electric currents.

We have hitherto supposed electricity to be either immovably associated with perfectly non-conducting matter, or collected on the bounding surfaces of conducting and non-conducting media in such a way that the force tending to cause it to move is balanced by an invincible resistance. We have now to consider what happens when there is a finite unbalanced resultant force at any point in a conducting medium. If a conducting sphere of radius a be charged with Q units of positive electricity, its potential will be $\frac{Q}{a}$. Connect this sphere by a long thin wire, whose capacity may be neglected, with another uncharged sphere of radius b, then we know that the potentials of the two spheres become equal; and since what we call electricity is subject to the law of continuity, the whole charge on the two spheres must be the same as before. Hence if U be the common potential, we must have $U = \frac{Q}{a+b}$. It appears, therefore, that the potential of a has fallen by $\frac{b}{a+b}\,\frac{Q}{a}$, and an amount $\frac{b}{a+b}Q$ of positive electricity has passed from a to b, and also a $\frac{b}{a+b}$th part of the electric potential energy has disappeared. In accordance with our hypothesis that electricity obeys the law of continuity like an incompressible fluid, we explain this transference of electricity by saying that an electric current has flowed through the wire from the place of higher to the place of lower potential. We define the intensity or strength C of the current as the quantity of electricity which crosses any section of the wire in unit of time.

Owing to the law of continuity the current intensity is of course the same at every point of a linear conductor. In the case which we have just given, the whole transference takes place in so short a time that we cannot study the phenomenon in detail. It is obvious that C will vary rapidly from a large initial value, when the difference between the potentials of the spheres is $\frac{Q}{a}$, to zero when they are at equal potentials. It is possible, by replacing the wire by wetted string or other bad conductor, to prolong the duration of the phenomenon to any extent, so that C should vary very slowly; and we can imagine cases where C would remain constant for a long time. Machines for producing a continuous or "steady" current have been invented in considerable variety, the first of the kind having been the Pile of Volta. Of such machines we shall have more to say when we come to discuss Electro-motive Force. We have seen, in the case of our spheres, that the passage of the electric current was accompanied by a loss of potential energy. The question thus arises, what becomes of the energy after the current dies away, and the equalization of potential is complete? This leads us to look for transformations of energy depending on the electric current, or, in other words, to look for dynamical effects of various kinds due to it. Accordingly we find the passage of the electric current accompanied by magnetic phenomena, sparks, heating of the circuit, chemical decompositions, mechanical effects, etc. All these are observed in the discharge of the Leyden jar and other electro-static reservoirs of potential energy. Exactly similar effects, some more, others less powerful, are observed accompanying the current of the voltaic battery and other machines which furnish a steady flow of electricity. In all such cases we have (1) a source of energy, (2) a flux of electricity, (3) an evolution of energy in different parts of the circuit. We reserve the consideration of (1) for the present, as being the most difficult, and devote our attention to (2) and (3).

Application of principle of conservation of energy.

Ohm's Law applied to Metallic Conductors.

Measurement of currents.

We have already seen how to measure the strength of an electric current in a linear conductor. According to the definition we gave above, the unit current strength would be that for which a unit of electricity passes each section of the conductor in unit of time. If the unit of electricity is the electro-static unit, this is called the electro-statical unit of current. We have supposed above that the current consists in the transfer of a certain amount of + electricity in a certain direction, which we shall call the *positive direction* of the current, and this for most purposes is convenient. We must remember, however, that no distinction can be drawn between the transference of +Q units of electricity in one direction and the transference of −Q units in the opposite direction; for we have no experimental evidence on which such a distinction can be founded.

Electromagnetic measure.

We may measure the current by any one of its various effects. The method most commonly used, both for indicating and measuring currents, is to employ the magnetic effect. According to Oersted's discovery, a magnetic north pole placed in the neighborhood of a straight current is acted on by a force such that, if the pole were to continually follow the direction of the force, it would describe a circle round the current as an axis, the direction of rotation being that of the rotation of a right-handed cork-screw which is traversing a cork in the positive direction of the current. If, therefore, we have currents of different strength in the same wire, the force exerted on a magnet which always occupies the same position relatively to the wire will be a measure of the current. The force exerted on the magnet may be found by balancing it against known forces, or by allowing the magnet to oscillate under it and finding the time of oscillation. It is easy, by applying the law of continuity to multiple circuits, to verify that the measure of current intensity thus got is proportional to the electro-static measure.

Thus let AB (fig. 18) be a circuit splitting up into two exactly similar branches BCDG, BEFG, and uniting again at G. Then, since electricity behaves like an incompressible fluid, it is obvious that any current of intensity C in AB will split up into two currents each of intensity ½C in CD and EF. By placing a magnet in similar positions at the same distance with respect to AB, CD, and EF, it will be found that the magnetic action in the last two positions is just half that in the first.

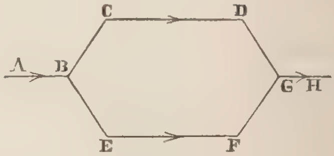

Fig. 18.

Electromagnetic unit.

The appropriate unit in magnetic measurements of current intensity is that current which, when flowing in a circular arc of unit radius and unit length, exerts unit of force on a unit north pole placed at the centre of the arc, the unit north pole being such that it repels another equal north pole at unit distance with unit force. This is called the *electromagnetic unit* of current intensity. Unless the contrary is stated, all our formulæ are stated in terms of this unit.

Galvanometer.

To facilitate the detection and measurement of currents by magnetic means, an instrument called a galvanometer is used. It consists of a coil of wire, of rectangular, elliptical, or circular section, inside which is suspended a magnetic needle, so as to be in equilibrium parallel to the coil windings under the magnetic action of the earth, or of the earth and other fixed magnets. When a current passes through the coil a great extent of the circuit is in the immediate neighborhood of the magnet, and the magnetic action is thus greatly accumulated. See article GALVANOMETER.

Electromotive force, resistance, and current strength.

If we connect two points A and B of a homogeneous linear conductor, every point of which is at the same temperature, by two wires of the same metal to the electrodes of a quadrant electrometer, then if a steady current C (measured in *electro-static* units) be flowing from A to B, we shall find that the potential at A is higher than that at B by a certain quantity E, which we may call the *electro-motive* force between A and B, and we may suppose E for the present to be measured in electro-static units. If we examine the value of the ratio $\frac{E}{C}$ for different positions of the points AB, we shall find that it varies directly as the length of linear conductor between A and B, provided the section of the conductor is everywhere the same. If we try wires of different section, but of the same length and the same material, we find that $\frac{E}{C}$ is inversely proportional to the sectional area; in fact we may write

Ohm's law, $\frac{E}{C}=R$.

$$\frac{E}{C}=R=\frac{kl}{\omega}, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where l denotes the length of the wire, ω its section, and k a constant depending on its material, temperature, and physical condition generally. This is Ohm's law.

In whatever unit measured, R is called the resistance of the conductor. The unit of resistance can always be conceived as established by means of a certain standard wire. The unit of electro-motive force is then such that if applied at the end of the standard wire it would generate a unit current in the wire. The constant k is called the *specific resistance* of the material of which the wire is made; it is obviously the resistance of a wire of the material of unit length and unit section.

Dimensions of units.

In the electro-static system of unitation the unit of E is the work done by a unit particle of + electricity in passing to infinity from the surface of an isolated sphere of radius unity charged with an electro-static unit of + electricity. The dimension of E is $\left[QL^{-1}\right]$, where $\left[Q\right]$ is the dimension of the electro-static unit of quantity (see p. 21), $\left[Q\right]=\left[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}\right]$. Hence the dimension of E is $\left[L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\right]$. The unit of C we have already discussed; its dimension is $\left[QT^{-1}\right]=\left[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}\right]$. From these results, and equation (1), it follows that the dimension of R is $\left[L^{-1}T\right]$, *i. e.*, that of the reciprocal of a velocity. We shall show hereafter that, if C be measured in electro-magnetic units, its dimension is $\left[L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}\right]$; hence that of Q is $\left[L^{\frac{1}{2}}M^{\frac{1}{2}}\right]$, the unit of Q being the quantity of electricity conveyed across any section by the unit current. Also ECT = work done in time T in conveying C units of + electricity from potential V + E to potential V, whence [ECT] = dimension of energy $=\left[L^{2}MT^{-2}\right]$. Hence $\left[E\right]=\left[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}\right]$. In this case then $\left[R\right]=\left[LT^{-1}\right]$; so that in electro-magnetic measure R has the dimension of a velocity.

Ohm's law generalized.

We can put the equation (1) into another form, which suggests at once the generalization of Ohm's law for any conductor. Consider two points P and Q on a linear conductor, at a distance dx from each other, x being measured in the direction of the current. Let the potentials at P and Q be V and V + dV, then E = − dV. If u denote the current per unit of area of the section, then $C=u\omega$, and since $l=dx$ we have $R=\frac{kdx}{\omega}$. Substituting these values in (1) we get

$$u=-\frac{1}{k}\frac{dV}{dx}=\frac{X}{k}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where X is the component electric force at P in the direction of the current. Since the electric current is of the nature of a flux, it is determined at any point of a conductor by the flux components uvw, representing the quantities of electricity which in unit of time cross three unit areas perpendicular to three rectangular axes drawn through P. If X, Y, Z be the components of the electric force at P, then the general statement of Ohm's law for a homogeneous isotropic conductor is

$$u=\frac{X}{k}, \quad v=\frac{Y}{k}, \quad w=\frac{Z}{k}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

In such a conductor the resistance of a small linear portion of given dimensions, cut out of the substance any where or any how, will be the same. It is conceivable, however, that the resistance of such a small portion would be different if cut in different directions at any point, in which case the conductor would be æolotropic. The most general statement of Ohm's law would then be

Equations of conduction.

$$\left.\begin{aligned} u&=r_1X+p_3Y+q_2Z \\ v&=q_3X+r_2Y+p_1Z \\ w&=p_2X+q_1Y+r_3Z \end{aligned}\right\}, \quad . \quad . \quad . \quad . \quad (4)$$

where r_1, etc., p_1, etc., q_1, etc., are constants for any one point. If they are the same for all points, the body is said to be homogeneous; if they vary from point to point, the body is said to be heterogeneous. If we may liken our conductor to an arrangement of linear conductors (see Maxwell, §§ 297, 324, vol. i.), then it may be shown that the skew system of (4) becomes symmetrical, inasmuch as $p_1=q_1$, $p_2=q_2$, $p_3=q_3$. The great majority of the substances with which the electrician has to deal are, however, isotropic; and unless the experiments of Wiedemann on certain crystals point to æolotropic conduction, we do not know of any case which has been experimentally examined. The reader will find interesting developments of the subject in Maxwell, vol. i. § 297 *sqq.*

A very important remark to be made with regard to the equations (4) is that, being linear, the principle of superposition applies. Thus, if u, v, w be the current components due to electric forces X, Y, Z and u', v', w' similar components for X′, Y′, Z′, then the current for X + X′, Y + Y′, Z + Z′ is given by $u+u'$, $v+v'$, $w+w'$. It is obvious, moreover, that (4) are the most general equations that can be written down to connect current with electro-motive force, subject to the condition that the currents due to superposed electric forces are to be found by the superposition of the currents due to the separate forces.

Besides the equations (4), u, v, w are subject like any other flux components to an equation of continuity. This equation, investigated in the usual manner, is

$$\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz}+\frac{d\rho}{dt}=0, \quad . \quad . \quad . \quad (5)$$

where ρ is the electric volume density at the time t. At a surface of discontinuity (5) must be replaced by

$$(u-u')l+(v-v')m+(w-w')n-\frac{d\sigma}{dt}=0, \quad . \quad (6)$$

where u, v, w, and u', v', w' are components of flux on the first and second sides of the surface, l, m, n the direction cosines of the normal drawn from the first to the second side, and σ the electric surface density at time t.

If we consider the particular case of homogeneous isotropic media, and suppose further that $X=-\frac{dV}{dx}$, $Y=-\frac{dV}{dy}$, $Z=-\frac{dV}{dz}$, these equations reduce to

$$\frac{d^2V}{dx^2}+\frac{d^2V}{dy^2}+\frac{d^2V}{dz^2}=k\frac{d\rho}{dt}, \quad . \quad . \quad . \quad . \quad (7)$$

and

$$-\frac{1}{k_1}\frac{dV_1}{d\nu}+\frac{1}{k_2}\frac{dV_2}{d\nu}=\frac{d\sigma}{dt}. \quad . \quad . \quad . \quad . \quad (8)$$

In the last equation V_1 and V_2 are the potentials on the two sides of a boundary between media of specific resistance k_1 and k_2.

In the particular case of steady motion, the right-hand sides of (7) and (8) are zero. The analytical treatment of problems about steady currents is therefore precisely analogous to that of problems about electro-statical equilibrium, steady flow of heat, hydrodynamics, etc.: to every solution in one such physical subject corresponds a solution in each of the others. Many valuable details on this subject are to be found in Thomson's papers on electro-statics and magnetism.

Results of Ohm's law.

The consequences of Ohm's law have been followed out mathematically, and verified in a variety of cases. We shall notice a few which are interesting, either from the accuracy of the experimental results, or from the interest or practical importance of some method or principle involved.

Application to uniform linear conductors.

In the case of a steady current in a uniform linear conductor, say a wire, it is obvious that the potential must fall uniformly in the direction in which the current is flowing. Hence, if we suppose the wire stretched out straight, and erect at different points lines perpendicular to it, representing the potential at each point, the locus of the extremities of these lines will be a straight line.

This may be arrived at by integrating equation (5), which becomes in this case $\frac{d^2V}{dx^2}=0$, x being measured along the wire supposed to be straight; we thus get for the potential V, at any point distant x from the origin, at which potential is V_0,

$$V=V_0-\frac{Ck}{\omega}x. \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

If V be taken as ordinate, this represents a straight line, the tangent of whose inclination to the x-axis is $-\frac{Ck}{\omega}$, or $-uk$.

Voltaic circuit.

We cannot apply Ohm's law at the junction of two different substances. The condition of continuity of course applies; in other words, if the flow has become steady, the current is the same at all points of the circuit, whether homogeneous or not. We shall see, when we come to discuss electro-motive force, that there is a constant difference between the potentials at two points infinitely near each other, but on opposite sides of the boundary between two conductors of different material. If we knew this potential difference for each point of heterogeneous contact in the circuit, we could draw the complete potential curve for the circuit by applying Ohm's law to each conductor separately. The diagram (fig. 19) represents (on the contact theory, as held by Ohm, see Origin of Electro-motive Force) the fall of potentials and the discontinuities in a voltaic circuit, consisting of zinc, water, and copper, in which the current flows from Cu to Zn across the junction of the metals. We assume for the present that Ohm's law applies to the liquid conductor.

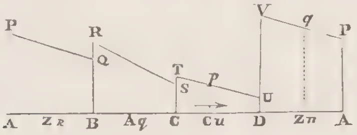

Fig. 19.

Let us denote by V_Q, V_R, etc., the potentials at Q and R, etc., or what is the same thing, the ordinates BQ, BR, etc., in our diagram. Then applying Ohm's law to the homogeneous parts of the circuit, we have $V_V - V_Q = CR'$, $V_R - V_S = CS$, $V_T - V_U = CR''$, where R′, S, R″, denote the resistances of the zinc, the water, and the copper respectively. Now, denoting $V_V - V_U$, the potential difference, or as it is sometimes called, "the contact force" between Zn and Cu by E_{ZC}, and so on, let us add the above three equations; we thus get

$$E = E_{ZC} + E_{AZ} + E_{CA} = C(R' + R'' + S).$$

Here E is called the *whole electro-motive force* of the circuit, being the sum of all the discontinuities of potential, taken with their proper signs, or, what is equivalent to the same thing, the whole amount of work which would be done by a unit of + electricity, in passing round the whole circuit once, supposing it to get over the discontinuities without gain or loss of work. Defining E in this way, we may extend Ohm's law to a heterogeneous circuit, the resistance R being now the sum of all the resistances of the different parts, or the whole resistance. In accordance with this definition, if we take two points, *p* and *q* (fig. 19) in the Cu and Zn respectively, the whole electro-motive force will be $V_p - V_q + E_{ZC}$, and the current will be given by

$$V_p - V_q + E_{ZC} = RC, \quad . \quad . \quad . \quad . \quad (10)$$

where R is the whole resistance of *pq*. $V_p - V_q$ is sometimes called the "external," and E_{ZC} the "internal" electro-motive force. If *p*, *q* include more than one contact of heterogeneous metals, we have only to add on the left-hand side of (10) the corresponding internal electro-motive force for each discontinuity.

If *p* and *q* be connected by wires of the same metal, say copper, to the electrodes of a Thomson's electrometer, then the electrometer will indicate a potential difference, $V_p - V_q + E_{ZC}$, and not $V_p - V_q$, as might at first sight be suspected.[1] No electricity can flow through the electrometer, hence the copper wire attached at *p*, and the pair of quadrants to which it leads (we may suppose the quadrants made of copper, but in reality it does not matter, see below, Origin of Electro-motive Force), will be at potential V_p. But owing to the contact force between the Zn and Cu at *q*, the wire from *q* and the quadrant to which it leads will be at potential $V_q + E_{ZC}$. It appears, therefore, that the electrometer indication corresponds to the *whole* electro-motive force between *p* and *q*, and is proportional to the whole resistance between *p* and *q*, no matter what metals the circuit may include.[2] This conclusion was verified by Kohlrausch. His method rested on the principal of Volta's condensing electroscope.

Verification by Kohlrausch.

He used an accumulator consisting of a fixed plate B, and an equal movable plate A, which could be lowered to a very small fixed distance from B, and raised to a considerable distance, so as to touch a fixed wire leading to a Dellmann's electrometer. The plate A was lowered and connected with *p*, while *q* and the fixed plate were connected with the ground; the connection with *p* was then removed, and A raised, its potential thereby greatly increasing owing to its greatly diminished capacity. This increased potential was measured by the electrometer, with which A was in connection through the fixed wire. In one of Kohlrausch's experiments, he found for the electromotive force between a fixed point of the metallic circuit and four points, such that the resistance between each adjacent pair was very nearly equal, the values 0·85, 1·81, 2·69, 3·70; the values calculated by Ohm's law were 0·93, 1·86, 2·80, 3·73. He also examined the fluid part of the circuit, and still found a good agreement between theory and experiment. (See Wiedemann, § 102.)

Network of linear conductors.

The laws of current distribution in a network of linear circuits were first studied by Kirchhoff. He laid down two general principles which are very convenient in practical calculations.

I. The algebraical sum of all the currents flowing from any node of the network is zero.

II. If we go round any circuit of the network, then no matter how many meshes it may include, or what conductors may branch off at different parts, we have

$$E - R_1C_1 + R_2C_2 + \ . \ . \ . \ . \ R_nC_n,$$

where E is the *whole internal electro-motive* force, and R_1, R_2 . . . . C_1, C_2 . . . . are the resistances and current strengths in the different parts of the circuit.

The first of these principles is simply the law of continuity, and the second is got at once by applying equation (10).

We give here an investigation of the currents and potentials in a network of conductors. The method and notation are taken from Maxwell, vol. i. § 280. Let A_1, A_2 . . . A_n be *n* points, connected by a network of $\frac{1}{2}n(n-1)$ conductors (that being the number of different pairs of conductors that can be selected from the *n*). Let C_{pq}, E_{pq}, K_{pq} denote the current strength, internal electro-motive force, and *conductivity*, *i. e.*, the reciprocal of the resistance, for the conductor $A_p A_q$. Let, moreover, the potential at A_p be P_p, and the current of electricity which enters the system there be Q_p. It is obvious from our definitions of the symbols that

$$K_{pq} = K_{pq}, \quad C_{pq} = -C_{qp}, \quad E_{pq} = -E_{qp},$$

and, by the condition of continuity, that

$$Q_1 + Q_2 + \ . \ . \ . \ . + Q_n = 0.$$

At the point A_p we have

$$C_{p1} + C_{p2} + \ . \ . \ . \ . + C_{pn} = Q_p. \quad . \quad . \quad . \quad . \quad (\alpha)$$

Now

$$C_{pq} = K_{pq}(P_p - P_q + E_{pq}). \quad . \quad . \quad . \quad . \quad (\beta)$$

Hence (α) becomes

$$\begin{aligned} K_{p1}(P_1 - P_p) + K_{p2}(P_2 - P_p) + \ . \ . \ . \ . + K_{pn}(P_n - P_p) \\ = K_{p1}E_{p1} + \ . \ . \ . \ . + K_{pn}E_{pn} - Q_p. \quad . \quad . \quad . \quad (\gamma) \end{aligned}$$

The symbol K_{pp} does not occur in this equation, and has no meaning as yet. Let us define it to mean $-(K_{p1} + K_{p2} \ . \ . \ . \ . \ K_{pn})$, where K_{pp} does not occur. Then we have

$$K_{p1} + K_{p2} + \ . \ . \ . + K + \ . \ . \ . + K_{pn} = 0, \quad . \quad . \quad (\delta)$$

and, multiplying by $P_p - P_r$,

$$K_{p1}(P_p - P_r) + \ . \ . \ . \ . + K_{pp}(P_p - P_r) \ . \ . \ . \ K_{pn}(P_p - P_r) = 0.$$

Adding this last equation to (γ) we get

$$\begin{aligned} K_{p1}(P_1 - P_r) + K_{p2}(P_2 - P_r) + \ . \ . \ . + K_{pn}(P_n - P_r) \\ = K_{p1}E_{p1} + \ . \ . \ . + K_{pn}E_{pn} - Q_p. \quad (\epsilon) \end{aligned}$$

In this equation the term whose coefficient is K_{pr} of course vanishes. By giving *p* all possible values except *r*, we get a set of $n-1$ equations to determine the $n-1$ quantities $P_1 - P_r$, $P_2 - P_r$, etc. Hence if M_{rr} denote the minor of K_{rr} in the determinant $\Delta = (K_{11}K_{22} \ . \ . \ . \ . \ K_{nn})$;[3] and if M_{rrp} denote the minor of K_{pq} in M_{rr}, we have

$$\begin{aligned} (P_p - P_r)M_{rr} = \{K_{11}E_{11} + K_{12}E_{12} + \ . \ . \ . + K_{1n}E_{1n} - Q_1\}M_{rr1p} \\ + \{K_{21}E_{21} + K_{22}E_{22} + \ . \ . \ . \ . \ . \ . \ . \ . \ . \ {}_2 - Q\}M_{rr2p} \\ + \text{etc.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\zeta) \end{aligned}$$

---

[1] It is supposed that all the wires are at the same temperature.

[2] This more general statement follows at once from the above reasoning in conjunction with Volta's law (*cf.* below, Origin of Electro-motive Force).

[3] This determinant has many properties of interest to the mathematical student; *e.g.*, in our notation $M_{11} = M_{22} \ . \ . \ . = M_{nn}$, $M_{rrsp} - M_{rrtp} = M_{p\cdot sr} - M_{pptr}$, etc. etc.

where of course E_{11} and E_{22} are zero, and M_{rrrp} does not occur. This expression is linear in the letters E and Q, and the principle of superposition holds, as we saw it ought to do in all applications of Ohm's law.

Consider the particular case in which all the Qs and Es vanish, except E_{lm} and E_{ml} $(=-E_{lm})$, we then have the case of a linear circuit in which an electro-motive force E_{lm} is introduced into A_lA_m. We get from (ζ)

$$P_p - P_r = \frac{K_{lm}E_{lm}}{M_{rr}}(M_{rrlp} - M_{rrmp}),$$

and

$$P_q - P_r = \frac{K_{lm}E_{lm}}{M_{rr}}(M_{rrlq} - M_{rrmq}).$$

Hence

$$P_p - P_q = \frac{K_{lm}E_{lm}}{M_{rr}}(M_{rrlp} - M_{rrlq} - M_{rrmp} + M_{rrmq}),$$

and

$$C_{pq} = \frac{K_{pq}K_{lm}E_{lm}}{M_{rr}}(M_{rrlp} - M_{rrlq} - M_{rrmp} + M_{rrmq}). \quad (\eta)$$

Similarly, if C_{lm} be the current in A_lA_m due to an electro-motive force E_{pq} in A_{pq}, we get

$$C_{lm} = \frac{K_{lm}K_{pq}E_{pq}}{M_{rr}}(M_{rrpl} - M_{rrpm} - M_{rrql} + M_{rrqm}). \quad (\theta)$$

Now, since Δ is a symmetrical determinant, $M_{rrlp} = M_{rrpl}$, etc., and the expressions within brackets in (η) and (θ) are indentical. Hence follows the important proposition:—

If an electro-motive force equal to unity, acting in any conductor A_lA_m of a linear system, cause a current C to flow in the conductor A_pA_q, then an electro-motive force equal to unity, acting in A_pA_q, will cause an equal current C to flow in A_lA_m.

If we suppose all the conductors of the system except A_lA_m and A_pA_q removed, and A_lA_p and A_mA_q joined by two wires, in such a way that for electro-motive force unity in A_lA_m the current in A_pA_q is C, then the conductivity of the circuit which we have thus constructed would be

$$\frac{K_{lm}K_{pq}}{M_{rr}}(M_{rrpl} - M_{rrpm} - M_{rrql} + M_{rrqm});$$

Conjugate conductors.

this might be called the reduced conductivity of the system with respect to A_pA_q and A_lA_m. When the expression within brackets vanishes the conductors A_pA_q and A_lA_m are said to be conjugate. The reduced resistance in this case is infinite, and no electro-motive force in A_lA_m, however great, will produce any current in A_pA_q, and reciprocally.

Similarly, we may prove that if unit current enter a linear system at A_l and leave it at A_m, the difference of potential thereby caused between A_p and A_q is the same as that caused between A_l and A_m, when unit current enters at A_p and leaves at A_q. (See Maxwell.)

Multiple arc.

The case of several wires forming a multiple arc very often occurs in practice. Let AB, CD (fig. 20) be two parts of a circuit whose resistances are R and S, and let the circuit branch out between B and C into three branches of resistances R_1, R_2, R_3.

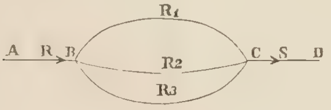

Fig. 20.

We have $V_B - V_C = R_1C_1 = R_2C_2 = R_3C_3$, and

$$C_1 = \frac{\frac{1}{R_1}C}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}}, \quad C_2 = \text{etc.}$$

Also

$$V_A - V_D = V_A - V_B + V_B - V_C + V_C - V_D = (R + \rho + S)\,C,$$

where

$$\frac{1}{\rho} = \frac{1}{R_1} + \frac{1}{R} + \frac{1}{R_3}.$$

Hence the current in each branch is inversely proportional to the resistance, that is, directly proportional to the *conductivity;* and the reduced conductivity of the multiple arc is equal to the sum of the conductivities of its branches. These statements are obviously true for any number of branches.

Resistance measurement.

Some of the most important applications of the theory of linear circuits occur in the methods for comparing resistances. The earliest method for doing this consisted simply in putting the two conductors, whose resistance it was required to compare, into a circuit which remained otherwise invariable; if the current, as measured by a galvanometer, was the same, whichever conductor was in the gap, it was concluded that their resistances were equal. The difficulty in this method is that the electro-motive force and internal resistance of the battery are supposed to remain constant, a condition which it is excessively hard to fulfil.

Differential galvanometer.

This difficulty can be avoided by using a differential galvanometer, or the arrangement of conductors called Wheatstone's bridge. The differential galvanometer differs from an ordinary one simply in having two wires wound side by side instead of a single wire. If we pass equal currents in opposite directions through the two wires, the action on the needle is zero, provided the instrument be perfectly constructed. If the currents are unequal, the indication will be proportional to the difference of the current strength.

If the coils are not perfectly symmetrical, but such that the deflection[1] due to a current c in one is mc, and in the other nc, where m and n are the "constants" of the two coils, then the deflection for currents c_1 and c_2 is $mc_1 - nc_2$.

Fig. 21 gives a scheme of the arrangement for measuring resistances with this instrument. V is the battery inserted in the common branch ED of the two circuits, which convey currents dividing off at D, and going in opposite directions round the coils of G. If we wish to measure the resistance of a wire, it is inserted at AB by means of binding screws or mercury cups, and the resistance of the other circuit is varied until there is no deflection; then AB is replaced by a known resistance, which is made up until there is zero deflection as before.

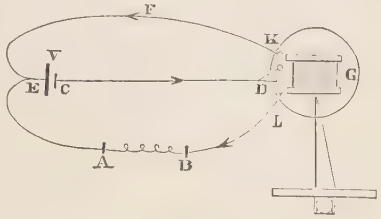

Fig. 21.

It is obvious that the only requisite here is that the resistances of EFK, EA, BL, and the galvanometer coils should remain constant. Variations in the electro-motive force or internal resistance of the battery do not affect the result.

The method which we have thus sketched is the best way of using the differential galvanometer, and it does not matter even if the coils are not exactly symmetrical. Let the constants of the coils M and N be m and n, so that the deflection due to currents c_1 and c_2 in M and N is $mc_1 - nc_2$. Let the resistance from E to D in the single branch be B, and in the circuits EFK and EABL, which pass round M and N respectively, R and S + U, U being the resistance between A and B, which is such that the deflection is zero. Then

$$0 = mc_1 - nc_2 = \left\{ m(S+U) - nR \right\} \frac{E}{D}, \quad . \quad . \quad . \quad . \quad (\alpha)$$

where E is the electro-motive force of the battery, and

$$D = (R + S + U)B + R(S + U).$$

Suppose we substitute U′ for U, and arrange U′ so that we have again zero deflection. Then

$$0 = \left\{ m(S + U') - nR \right\} \frac{E'}{D'}. \quad . \quad . \quad . \quad . \quad . \quad (\beta)$$

From α and β we get U = U′.

For farther details concerning this method, see Maxwell, vol. i. § 346, and Schwendler, *Phil. Mag.*, 1867.

Wheatstone's bridge.

The differential galvanometer method was much used by Becquerel and others, but it is now entirely superseded as a practical method in this country by the Wheatstone's bridge method. Suppose we have a circuit ABDC of four conductors.

---

[1] The deflections are supposed small.

Insert a galvanometer G between B and C, and a battery between A and D. Adjust say the resistance AB until the galvanometer in BC indicates no current. The bridge is then said to be balanced, and the potentials at B and C must be equal. But the whole fall of potential from A to D along ABD is the same as that along ACD; hence if the fall from A to B is to be equal to that from A to C, we must have

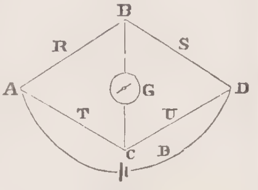

Fig. 22.

$$\frac{\mathrm{R}}{\mathrm{S}} = \frac{\mathrm{T}}{\mathrm{U}},$$

where R,S,T,U are the resistances in AB, BD, CA, DC. This is the condition that BC and AD be conjugate. We might have deduced it as a particular case of the general theory given above. Hence if we know the resistances S,T,U, we get in terms of these $\mathrm{R} = \frac{\mathrm{ST}}{\mathrm{U}}$. S is often called the standard resistance, and T, U the arms of the bridge or balance. The sensibility of this arrangement may be found practically by increasing or decreasing R so as to derange the balance. The largest increase which we can introduce without producing an observable galvanometer deflection measures the sensibility of the bridge.

Arrangement for maximum sensibility.

If we had a given set of four conductors, and a battery and galvanometer of given resistance, then it may be shown (see Maxwell, vol. i. § 348) that the best arrangement is that in which the battery or galvanometer connects the junction of the two greatest resistances with that of the two least, according as the former or the latter has the greater resistance. The practical problem might take another form. We might have given a resistance, and have at our disposal known resistances of any desired magnitude to form our bridge. We might also suppose further that we had given the total area of the plates of our battery, and the dimensions of the channel in which the galvanometer wire was to be wound. We may neglect the thickness of the silk coating, or assume that it is proportional to the thickness of the wire.

Then, B and G being the resistances of the battery and galvanometer, the electromotive force $\mathrm{E} \propto \sqrt{\mathrm{B}}$, and the number of turns in the galvanometer $\propto \sqrt{\mathrm{G}}$.

Let us put $\mathrm{S} = y\mathrm{R}$, $\mathrm{T} = z\mathrm{R}$, and $\mathrm{U} = yz\mathrm{R}$. These resistances would balance; let us however put $(1 + x)\mathrm{R}$ in the branch AB instead of R, the others being unchanged, and calculate the effect on the galvanometer in G, which we put proportional to the current in BC, and to the number of turns on galvanometer. Then, from equation (η) (or Maxwell, vol i. 349), we find that the deflection δ varies as

$$\frac{yz\sqrt{\mathrm{BG}}}{(1+y)(1+z)\mathrm{BG} + y(1+z)^2\mathrm{BR} + z(1+y)^2\mathrm{GR} + yz(1+y)(1+z)\mathrm{R}^2};$$

in order that δ may be a maximum, we must have

$$\mathrm{G}\{(1+y)(1+z)\mathrm{B}+z(1+y)^2\mathrm{R}\}=y(1+z)^2\mathrm{BR}+yz(1+y)(1+z)\mathrm{R}^2, \quad (\alpha)$$

$$\mathrm{B}\{(1+y)(1+z)\mathrm{G}+y(1+z)^2\mathrm{R}\}=z(1+y)^2\mathrm{GR}+yz(1+y)(1+z)\mathrm{R}^2, \quad (\beta)$$

$$\mathrm{BG} = z\mathrm{R}^2, \quad . \quad . \quad . \quad . \quad (\gamma)$$

$$\mathrm{BG} = y\mathrm{R}^2. \quad . \quad . \quad . \quad . \quad (\delta)$$

α and β give at once by addition and subtraction

$$\frac{\mathrm{B}}{\mathrm{G}} = \frac{z(1+y)^2}{y(1+z)^2} \text{ and } \mathrm{BG} = yz\mathrm{R}^2,$$

or

$$\mathrm{B} = z\frac{1+y}{1+z}\mathrm{R}, \quad . \quad . \quad . \quad . \quad (\epsilon)$$

$$\mathrm{G} = y\frac{1+z}{1+y}\mathrm{R}. \quad . \quad . \quad . \quad . \quad (\zeta)$$

Combining the four equations (γ), (δ), (ϵ), (ζ), we get

$$y = z = 1 \text{ and } \mathrm{B} = \mathrm{G} = \mathrm{R} = \mathrm{S} = \mathrm{T} = \mathrm{U}.$$

It appears, therefore, that when all the resistances on the bridge are at our disposal, we ought to make them all equal to the resistance to be measured, or come as near this as we can; *e.g.*, if we had a very small resistance to measure, we should make the arms of the bridge small, and take a small-resistance in preference to a high-resistance galvanometer.

Standards of resistance.

In order to carry out measurements of resistance with ease we must possess a series of graduated resistances, with which we can compare any unknown resistance, and of which we can make the arms of our balance, etc. Again, if the measurements of one electrician are to be of any use to another, there must be a common standard. It would be most convenient to have only one standard for all nations, and this standard might be either arbitrary, like the standard of length, or absolute in some sense such as we have defined above. Arbitrary standards have at different times been proposed by Jacobi and others. The mercury standard of Siemens, to which we alluded in the historical sketch, has obtained great prevalence on the Continent. The British Association unit or ohm is an absolute unit, inasmuch as it professes to represent in electro-magnetic measure a velocity of 10^9 centimetres per second, or, taking the original definition of a metre, an earth quadrant per second. It happens, by a curious accident, that the mercury unit and the ohm are very nearly equal, the latter being expressed in terms of the former (according to Dehms and Hermann Siemens; see Wiedemann, Bd. ii. 2, § 1074) by the number 1·0493.

Rheostat.

One of the earliest instruments for furnishing a graduated resistance was the rheostat, brought into use by Wheatstone, but also invented independently by Jacobs at St. Petersburg about 1840.

It consisted of two cylinders of equal diameter, one of wood and one of brass. A wire, whose extremities were in connection with the metallic axes of the cylinders, was wound in opposite directions round the cylinders. The axes of the cylinders were connected with two binding screws by means of sliding contacts. The part of the wire which does *not* lie on the metal cylinder is the only part that produces resistance between the binding screws: and, by winding and unwinding, we can increase or diminish the resistance continuously to a known extent, means being provided for measuring the angular rotation of the metal cylinder.

Resistance boxes.

We shall not stop to consider the defects of this instrument, which is now never used for delicate work. Its place is taken by resistance boxes, containing coils of wire whose resistances are different multiples of the unit of resistance (in this country always the ohm). The reader will find a full account of the methods by which the standards are reproduced in the collected reports of the Committee on Electrical Standards. The usual material for the wire of resistance coils is German silver. Most of the copies of the ohm issued by the British Association were made of an alloy of two parts of silver to one of platinum. The great advantage of alloys is that the variation of resistance with temperature is small for them; in the PtAg alloy, for instance, it is less than a tenth of the value for an average pure metal. To secure insulation the wires are carefully coated with silk, and after winding the coil is immersed in melted paraffin. To get rid of electromagnetic and inductive effects, the wire on resistance-coils is doubled on itself before being wound, so that, when a current passes through the coil, there are always two equal and opposite currents at each point. The terminals are formed by stout pieces of copper rod, whose resistance is either included in the coil, or is so small that it may be neglected. The connections for small resistances are managed by means of mercury cups, with pieces of amalgamated copper at the bottom, on which the copper electrodes are made to press.

For ordinary purposes the coils are arranged in a box (fig. 23),

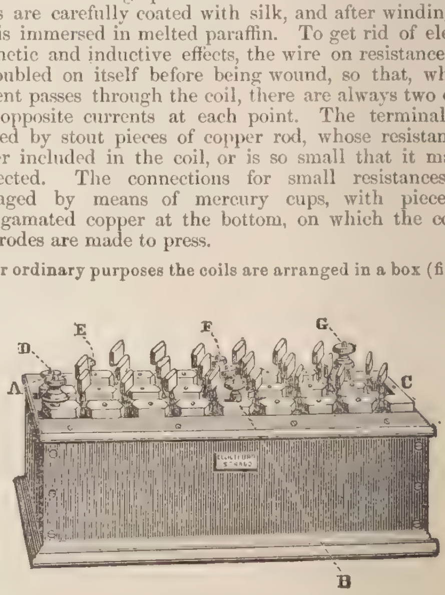

Fig. 23.

the terminals being stout pieces of brass fixed on the ebonite lid; conical brass plugs inserted between these pieces serve to throw the coils in and out of circuit. The box represented in fig. 23 is specially arranged for use in Wheatstone's bridge. In E, F, G we have a series of coils, 1000, 100, 10, 10, 100, 1000; these are used for the arms of the bridge. In A, C, D there are sixteen coils, 1, 2, 2, 5, 10, 20, 20, 50, etc., which give us any resistance of a whole number of ohms from 1 up to 10,000. In actual use the resistance to be measured is inserted between A and G, D and E are connected by a stout piece of copper, the galvanometer is inserted between F and A, and the battery between E and G. The resistances of the arms of the bridge are taken equal, and as near the resistance to be measured as possible. In this way the resistance of any conductor may be very quickly found to an ohm. If it is desired to go farther, we may proceed thus. Suppose that we have found that a resistance lies between 5 and 6, put in the arm FE 100, and in FG 10, let the resistance in DCA, when there is a balance, be 57, then the resistance of the conductor is $\frac{10}{100}\times 57$, or 5·7. Similarly we might go to a second place of decimals by putting 1000 in FE and 10 in FG. There is a limit, however, to this process, because the increase in the resistance of the arm decreases the "sensibility" of the bridge. Another method is to balance as nearly as possible, and then interpolate by taking the deflection of the galvanometer. Suppose, for instance, in the above case, that, with 5 ohms in DCA, the deflection was 21 in one direction, and, with 6 ohms, 9 in the other direction, then, taking the deflection proportional to the deviation from balance (see formula for δ above), we have

$$\text{resistance} = 5 + \frac{21}{30} \cdot 1 = 5{\cdot}7.$$

Conductivity boxes, reochord, etc.

We might also construct small graduated resistances; and this would enable us to use smaller arms in the bridge, and thus increase the "sensibility" when used to measure small resistances. Owing to the multiplication of connections, there is a limit to the ordinary resistance box arrangement. The difficulty may be evaded to a certain extent by using conductivity boxes, according to Sir W. Thomson's suggestion, where the resistances are arranged abreast, so that a small alteration of the resistance is brought about by adding on a *very great* resistance to the multiple arc. The rheostat principle has been used by Poggendorff in his rheocord for producing small resistances. He stretches two platinum wires side by side; on these is strung a hollow box filled with mercury, whose longitudinal motion is read off on a scale. If this arrangement be thrown into any circuit by means of two binding screws connected with adjacent terminals of the wires, the parts of the two wires up to the bridge give a small resistance, which may be adjusted at pleasure.

In the quicksilver agometer of Müller (Wiedemann, i. § 160), the resistance is formed by a column of mercury of variable length. We may remark here that difficulties equally arise in constructing very large resistances. To get such within reasonable compass the wire must be exceedingly thin and the insulation very good. Messrs. Warden and Muirhead have wound coils of fine wire, giving a resistance of 100,000, and have constructed in compact form resistance boxes up to 1,000,000, or a megohm, and beyond. They have also given practical form to a suggestion of Phillips to utilize the resistance of carbon, by drawing fine pencil lines on ebonite or glass; they mix plumbago with the pulp in the ordinary process of paper manufacture, and thus produce a species of carbon paper. A strip of this about 21 in. long and ·5 in. broad gives a resistance of about 50,000. This seems a valuable invention; but we are not aware how far it has stood the test of practical use.

Selenium and tellurium have been proposed as material for high resistances, but owing to the variability of their resistance under the action of light, etc., they are unfit for the purpose.

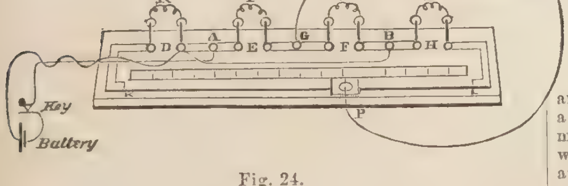

Fig. 24.

Kirchhoff's graduated wire, etc.

The best method for comparing resistances with great accuracy is the modification of Wheatstone's bridge introduced by Kirchhoff (fig. 24). KL is a platinum-iridium wire, DK and HL are stout copper terminals to which it is soldered, DAE, EGF, FBH are stout copper pieces with binding screws and terminals for mercury cups, by means of which resistances R, T, U, S can be inserted at D, E, F, H. A, B, and G are binding screws for the battery wires and one end of the galvanometer wire. The other end of the galvanometer wire is screwed to a spring contact piece fixed to a sliding block at P; when the button of this block is depressed, contact is made with KL, at a spot which is definite to an eighth or tenth of a millimetre. Platinum-iridium is chosen for KL, because it is hard and tough, not liable to be scratched or abraded by the contact piece, does not oxidize or amalgamate with mercury, and changes very slightly in resistance when the temperature alters. The wire must be calibrated to find what correction, if any, must be applied for variation of resistance per unit of length at different parts; for methods of doing this see Matthiessen and Hockin; *Brit. Assoc. Reports on Electrical Standards*, p. 117; or. Foster, *Journ. of Society of Telegraphic Engineers*, 1874.

Foster's method.

Kirchhoff's arrangement may be used in the ordinary way after we have made special experiments to determine the resistance of the connections, etc. Professor Foster (*l.c.*) has given a very useful method, by which the difference of two resistances can be got independently of the resistances of the connections. Suppose we wish to find the difference between R and S, which we suppose so near each other that, with the arms T and U approximately equal, there will be a balance when P is somewhere on KL. Let the reading for the position of the block be x, taken from left to right. Interchange R and S, balance again, and let the new reading be x' (we suppose the difference between R and S so small that P is still on KL); then, if μ be the resistance of unit length of KL, $R-S = \mu(x^1 - x)$.

For, if α represent the resistance of the connections in DK, β the same for the other end of the wire, and if T and U include the resistance of the invariable connections, then we have

$$\frac{R+\alpha+\mu x}{S+\beta+\mu(l-x)} = \frac{T}{U},$$

where $l =$ length of KL. Hence

$$\frac{R+\alpha+\mu x}{R+S+\alpha+\beta+\mu l} = \frac{T}{T+U}.$$

Similarly

$$\frac{S+\alpha+\mu x'}{R+S+\alpha+\beta+\mu l} = \frac{T}{T+U},$$

therefore

$$R-S = \mu(x'-x).$$

Methods of Mathiessen and Hockin and of Sir W. Thomson.

If we have to find the resistance of a thick cylindrical body, what is really wanted is the ratio of the current strength to the difference of potential between the two ends, when the current flows parallel to the axis at every point. The last condition is not generally fulfilled. It is obviously not so in the case where the cylinder is joined up with a thin wire. In cases where we wish to compare the specific resistance of two metals which we possess in cylindrical pieces, we get over the difficulty by observing the potential at a point at some distance from the end of the piece, where the flux is parallel to the axis at all points of the section.

Matthiessen and Hockin used the following method for this purpose (fig. 25). The two pieces XZ, YZ are soldered together and connected in circuit with two resistance coils A and C, and a graduated wire PR as before. S, S′ are two sharp edges, at a measured distance apart, fixed in a piece of ebonite or hard dry wood, and connected with mercury cups. T, T′ is a similar arrangement for YZ. The galvanometer is inserted between S and Q, and the position of Q is found for balance; then the terminal is shifted to S′, and if necessary the resistances A and C altered, so as to keep their sum constant, until balance is again found. The same is done for T and T′. Then, XS de-

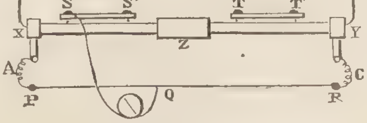

Fig. 25.

noting the resistance between X and S, and $A_{19}\,C_1$ the values of A and C in the first case, and so on, we have

$$\frac{XS}{XY}=\frac{A_1+PQ_1}{R},\ \frac{XS'}{XY}=\frac{A_2+PQ_2}{R},$$

where

$$R=A_1+C_1+PR=A_2+C_2+PR.$$

Hence

$$\frac{SS'}{XY}=\frac{A_2-A_1+Q_1Q_2.}{R}$$

Similarly

$$\frac{TT'}{XY}=\frac{A_4-A_3+Q_3Q_4}{R}.$$

Therefore

$$\frac{SS'}{T'T}=\frac{A_2-A_1+Q_1Q_2}{A_4-A_3+Q_3Q_4}.$$

This gives us the ratio of the resistances between SS′ and TT′. The method does not depend for its success on the goodness of the contacts at SS′, etc. Another ingenious arrangement for effecting a similar purpose is due to Thomson, and will be found described in Maxwell, vol. i. ⸹ 351.

Resistance measurement with electrometers.

In measuring very large resistances, such as the insulation resistance of a telegraph cable, it is convenient to use the quadrant electrometer. One end of the cable is connected with one electrode of a condenser, the other end of the cable is insulated, and the other electrode of the condenser put to earth. The condenser is charged, and the difference of potential between its electrodes measured by means of the electrometer. If E_1, E_2 be the value of the difference at the beginning and end of an interval of t seconds, and if S be the capacity of the condenser in electro-magnetic measure, then the resistance of the cable is

$$\frac{t}{S(\log_e E_1-\log_e E_2)}$$

in electro-magnetic measure. If the condenser itself leaks, we must determine its resistance by insulating the electrodes and operating as before. Then, regarding the circuit in the first experiment as a multiple arc, composed of the insulation of cable and the di-electric of condenser, the true conductivity of the cable envelope is the difference of the conductivities obtained in the two cases. Several other methods might be used to compare metallic resistances, but they are of small importance compared with those we have now been describing.

The reader who desires information concerning the application of Ohm's law to conductors other than linear will find the sources sufficiently indicated in Wiedemann's *Galvanismus;* some of them have been alluded to in the Historical Sketch.

Application of Ohm's Law to Electrolytes.

Electrolytic conduction.

In our discussion of Ohm's law, we have hitherto had in view principally the metallic part of the voltaic circuit. We now turn our attention more particularly to the fluid parts. It is of no importance in the present connection whether the fluid forms part of the "battery" or "electro-motor," or whether it is inserted outside the battery; the only difference in these two cases is, as we shall hereafter see, that in the former case energy is being absorbed by the current, and in the latter it is being evolved. In many respects the properties of the metallic and fluid parts of the circuit are alike: the electro-magnetic action is the same for both; heat is also developed in the body of the conductor, whether metallic or fluid, according to the same law. But there is one peculiarity about a large class of fluids which has no analogue in purely metallic conduction, viz., that in them the passage of a steady current of electricity is invariably accompanied by chemical decomposition, definite in kind and quantity. To such fluid substances Faraday gave the name of electrolytes.

For example, suppose we fill a small beaker with a solution of zinc chloride ($ZnCl_2$), and suspend in the liquid two strips of platinum foil (called *electrodes*), at a moderate distance apart. Let a current enter at one of these strips, which we shall call the anode, and leave at the other, which we shall call the cathode. It will be found that the solution continues to decompose so long as the current passes, zinc appearing at the cathode, and chlorine at the anode. The metallic zinc precipitates, and the chlorine combines with the platinum of the anode to form platinic chloride.

Faraday's law of conduction.

It is obviously essential in an electrolyte that it should be a compound in some sense or other. It is not, however, true that all compound bodies are electrolytes. Fluidity is also a necessary condition, whether attained by heating to the melting-point, or by dissolving in water or other solvent. Faraday established as a law, to which there appear to be few, if indeed any, exceptions,—*that all substances which in the solid state are very bad conductors, but conduct on being heated to the melting-point, are electrolytes,* i.e., *are decomposed by the passage of the electric current.* Faraday thought that periodide of mercury, fluoride of lead, and some other bodies were exceptions to this law; but later researches seem to have established that this is not so. (Cf. *Experimental Researches*, 414, 439, 1340, etc., and Wiedemann's *Galvanismus*, i. ⸹ 191, etc.) The conductivity of electrolytes in solution also increases rather quickly with increase of temperature, while the conductivity of metallic conductors, on the other hand, diminishes, but more slowly, as the temperature rises.

His law of electro-chemical equivalents.

In considering the passage of the currrent through electrolytes, it is convenient to distinguish two cases. First, let there be a steady, or at least permanent current, and a continuous evolution of the products of electrolytic decomposition (these are called the "*ions,*" anion and cation at the anode and cathode respectively). *The amount of ion that appears at an electrode in a second is equal to the strength of the current (supposed constant during a second) multiplied by a constant called the electro-chemical equivalent of the ion.*

The electro-chemical equivalent is proportional to the chemical equivalent, account being taken of the "*valency*" of the ion. (See art. ELECTROLYSIS.)

For instance, if C be the strength of the current in the illustrative case above, then the amount of zinc deposited at the cathode in time t will be zCt, and the amount of chlorine liberated at the anode cCt, where z and c the electro-chemical equivalents of zinc and chlorine, and $z : c :: \frac{65}{2} : 35{\cdot}5$, zinc being divalent. If a cell containing lead chloride ($PbCl_2$) were also inserted into the circuit, the same amount of chlorine would be liberated at the anode, and the amount of lead precipitated at the cathode would be pCt, where

$$p : z : c :: \frac{207}{2} : \frac{65}{2} : 35{\cdot}5,\ i.e. :: 103{\cdot}5 : 32{\cdot}5 : 35{\cdot}5.$$

Polarization and transition resistance.

As the electro-chemical decomposition ("electrolysis") goes on, the surface of the electrodes is altered. In some cases the ion is merely deposited on the electrode, in other cases it combines more or less intimately therewith; but in general there is an alteration of the nature of the contact, and a consequent alteration of the electro-motive force at the surface of the electrode. Experiment shows that this electro-motive force, in a great many cases, tends to oppose the passage of the current. So that if we insert an electrolyte into any circuit, the current starts with a certain value, and falls more or less quickly, until it reaches a limit at which it remains steady. The opposing electro-motive force of "polarization," as it is called, has then reached its maximum, and the deposition of the ions goes on without further alteration of the contact surfaces. It is obvious that this limit may be reached under a variety of different circumstances (*vide infra*, p. 81). There is also another phenomenon, the possibility of which we must not overlook, viz., an alteration of resistance, owing to the presence of the ions at the electrodes. This resistance, due to the ions, has been called the "transition resistance." The enfeebling of the current by the electro-motive force of polarization might, as far as the observed result is concerned, be due entirely to an increase of resistance, or to a transition resistance, and such was the explanation given by the earlier physicists. It is easy, however, to show that there is an actual electro-motive force of polarization; for, if we disengage our electrolytic cell from the battery, and connect its electrodes with a galvanometer, a current is indicated, which passes through the cell in the opposite direction to the original current. This could not be due to any transition resistance, but must arise from an opposing electro-motive force generated by the passage of the battery current. This point can be illustrated by a hydro-dynamical analogy. If we attempt to force water through a narrow capillary tube, or through a wide vertical tube against gravity, there is an opposing force in both cases. But, when we remove the pressure, the water has a tendency to return in the latter case, but none in the former. The former case represents a transition resistance, the latter an electro-motive force of polarization.[1]

Without denying the existence of a transition resistance, we see that an electro-motive force of polarization actually exists. In some cases, *e.g.*, amalgamated zinc in zinc sulphate, it is very small; in other cases, *e.g.*, platinum electrodes in dilute sulphuric acid, it may considerably exceed the electro-motive force of a Daniell's element.

We have, up to this point, been treating the case where a permanent current finally flows through the electrolyte; but there are cases where the existence of such a current would violate the principle of the conservation of energy.

Suppose that a single Daniell's cell is the electro-motor, then (see below, p. 85) if a current C is sent for a time t, an amount of energy dCt is absorbed in the cell, d being constant. Suppose, farther, that the excess of the intrinsic energy of the ions, in the state in which they are being delivered in the electrolytic cell, over that which they possess when in combination is w, then if a current C pass for a time t, an amount of energy wCt will be evolved. But if $w>d$, this cannot go on for any time however short, no matter how feeble the current may be, otherwise more energy would be evolved in the cell than is absorbed in the battery.

If we insert an electrolytic cell containing dilute sulphuric acid along with a galvanometer into a circuit in which there is a single cell of Daniell, we observe the galvanometer needle swing out vigorously, and then settle down to a small and gradually decreasing deflection. The current ultimately becomes zero;[2] but the time it takes to do so may be considerable, and varies with the nature of the electrodes. If we remove the battery after the current has stopped, and connect the polarized cell with the galvanometer, we observe an initial swing very nearly equal to the former, but in the opposite direction, and a corresponding deflection, which after a time disappears entirely. Although, as a rule, a sensible time elapses before the polarization reaches its maximum, yet it is important to remark that it may rise to a very considerable fraction of the maximum in a very short time indeed. Edlund[3] found that in a certain case the electro-motive force of polarization reached 0·57 of a Daniell in about $\frac{1}{50}$ of a second. Bernstein has recently arrived at results of a similar kind. He found, for instance, that platinum plates, polarized to 1·85 of a Daniell, fell, when the resistance of the circuit was 7·46 Siemens units, to 1·57 in ·00111 sec.[4] This rapidity of the rise and fall of the polarization is of very great importance, and has, we think, been overlooked by some experimenters.

In cases where the polarziation does not reach its maximum, no liberation of gas or other ion is observed, such as is seen with a permanent current, and it might of course be denied that chemical decomposition takes place at all. We shall, however, assume that Faraday's law holds for this case also, and assert that the current in the first instance actually passes through the liquid and produces chemical decomposition, according to the same law as a permanent current, and that this goes on until the accumulation of the ions has generated an opposing electro-motive force, equal to that of the battery, when of course the current must stop. We cannot justify this position very easily by direct experiment; yet there are many facts to support it, and so long as it is tenable it seems to afford the most philosophical view of the matter.

Having explained the phenomena of polarization so far as is necessary for our immediate purpose, we now proceed to inquire how far experience justifies the application of Ohm's law to electrolytes, or, which is much the same thing, to examine how far the methods of different physicists for measuring electrolytic resistance have led to concordant results.

Measurement of electrolytic resistance. Horsford.

One of the earliest methods, in which polarization was eliminated, was that of Horsford.[5] He filled a rectangular trough with the electrolyte, and inserted in the trough two electrodes very nearly fitting the cross section. These electrodes could be set at different measured distances apart. They were coated on the further side with non-conducting substance, so that the current could flow between the opposed sides only. In this way he secured that the stream lines in the neighborhood of the electrodes should depend as little as possible on the distance between them. This trough was inserted in the battery circuit along with a tangent galvanometer; then the distance between the plates was decreased, and a metallic resistance R inserted in the circuit, so as to bring the current to the same strength as before. The current being the same in both cases, it is assumed that the polarization in both is the same, in which case the resistance of a length of the electrolyte equal to the difference of the distances between the electrodes in the two cases is equal to R. Knowing the section of the trough, we might calculate from R the specific resistance of the electrolyte. If the values arrived at be the same when deduced from different lengths of the electrolyte, and for different strengths of current, it may be concluded that Ohm's law applies. The application of this method requires the passage of a permanent current, in consequence of which the ions appear at the electrodes, and the solution in the neighborhood becomes altered; so that it is difficult to make certain that the polarization is exactly the same in the two cases, and that no resistance of transition is generated. Matters may be mended a little by passing the current for the same time in both cases; but this is scarcely a satisfactory remedy. Still valuable results were obtained with this method by Horsford and Wiedemann; the latter, in applying it to silver and copper solutions used electrodes of silver and copper respectively whereby the polarization to be eliminated was very much reduced.

Beetz.

Taking advantage of the discovery of Matteucci and Du Bois Reymond,[6] that carefully amalgamated zinc electrodes in a *neutral*[7] solution of zinc sulphate are not polarizable, Beetz[8] determined, by means of Wheatstone's bridge, the resistance of various solutions of this electrolyte.

The liquid was inclosed in a cylindrical tube, 29·7 cm. long, with a mean section of 1·4051 sq. cm. Amalgamated zinc plates were applied to the ends of the tube, and fastened on by india-rubber collars. The ends were then inserted tightly into openings in the sides of two bottles which were filled with the solution (the same as that contained in the tube). The thick electrodes leading to the discs, and the backs of the zinc discs themselves, were lacquered, to insulate them from the liquid in the bottles. The whole apparatus was immersed in a trough of water, which could be heated to any desired temperature.

In the course of his experiments Beetz demonstrated the absence of polarization when amalgamated zinc electrodes are used, and eliminated the transition resistance by boiling the electrodes in zinc sulphate, and transferring them to the ends of the tube without exposure to the air.

Beetz farther proposed to find the specific conductivity of other electrolytes in terms of that of zinc sulphate, by experimenting on closed circuits consisting *entirely* of the electrolyte to be examined. He tried damping experiments for this purpose, but the effects to be observed turned out too small for accurate observation.

Paalzow.

Paalzow[9] inclosed the electrolyte to be examined in a siphon, the two ends of which dipped into vessels of porous clay also filled with the electrolyte. The clay vessels were immersed in beakers filled with zinc sulphate, at the bottoms of which were placed large amalgamated zinc discs, which formed the electrodes. The only polarization or transition resistance to be feared is that at the boundary of the two liquids, and this is very small. What little remained was eliminated, as in Horsford's method, by taking differences.

The resistance of the whole arrangement was measured by means of Wheatstone's bridge, and then the siphon was replaced by a shorter one filled with the same liquid. If R_1, R_2 be the resistances found in the two cases, $R_1 - R_2$ is obviously the resistance of a length of the electrolyte equal to the difference between the lengths of the siphons. If R_1', R_2' be similar values obtained when the electrolyte is replaced by mercury, then the specific resistance of the electrolyte is $\frac{R_1 - R_2}{R_1' - R_2'}$, that of mercury being taken as unity.

Kohlrausch and Nippoldt. Sine inductor.

The most important of all the recent researches on the application of Ohm's law to electrolytes are those of F. Kohlrausch and Nippoldt. In order to avoid the effects of polarization, they used the alternating currents of an electro-magnetic machine. These currents varied very nearly as the sine of the angle of rotation, and could be sent in rapid succession through the electrolyte. The whole quantity of electricity that passes in the first part of any alternation is exactly equal and opposite to that which passes in the second; hence equal quantities of the two ions (say H and O) will be separated at each electrode. If the H_2 and O combine to form water, it is obvious that, on the whole, there will be no resultant electro-motive force of polarization either way; and if they coexist side by side without combining, there will still be no *resultant* electro-motive force, provided the electrodes be exactly similar. There are two advantages in this method. There is no evolution of gas or other ion, and consequently no alteration of the solution and electrode, such as goes on with a constant current. We have, besides, another great advantage, which is denied[1] us with constant currents,—viz., that by increasing the *size* of the electrode, we can diminish the effects of polarization.

The whole amount of electricity which passes in each induction current is the same, and consequently the whole amount of ion deposited on the electrode is the same; hence, if we increase the surface of the electrode, the density of the deposit is decreased in an inverse ratio. Now, the researches of Kohlrausch and Nippoldt have shown[2] that, within certain limits, the electro-motive force is proportional to the surface density of the deposit. Hence, by sufficiently increasing the surface of the electrodes, the polarization may be made as small as we please.

In the earlier experiments platinum electrodes, having a surface of 1·08 cm. were used, and it was found that each induction current of the magneto-electric machine deposited on each square millimetre of the positive electrode only $\frac{1}{13,500,000}$ c.cm. of oxygen. It was therefore expected that the polarization would be insensible, and that the electrolyte would behave like a metallic resistance. The magneto-electric machine and the electrolyte were connected up with an electro-dynamometer, and it was found that the deflection of the suspended coil of the electro-dynamometer was scarcely sensible when the machine made 10 revolutions per second, although it was 15 scale divisions when the electrolyte was replaced by 70 Siemens units. On the other hand, when the velocity reached 77 revolutions per second, the deflection was much greater with the electrolyte than with 70 Siemens units. It was found, however, that when the surface of the electrodes was increased to 29 cm. a metallic resistance could be found, which gave the *same* deflection (within errors of observation) as the electrolyte for speeds varying from 4·8 to 76·9 revolutions per second.

The above results seem to compel us to one or other of two conclusions,—either that Ohm's law does not apply to rapidly alternating currents, where the maximum of polarization is not reached, or else that the electro-motive force of exceedingly small deposits of the ions must be very considerable. The fact that, under certain conditions, the electrolyte is apparently a better, and under others, apparently a worse conductor than a certain metal wire, seems at first sight rather to point to the former conclusion. On the other hand, the result with the 29 cm. electrodes is a direct verification of Ohm's law. Kohlrausch, therefore, adopted the latter conclusion, and justified his doing so by special researches on the electro-motive force of small gas deposits. He showed that, with the currents he used, the electro-motive force is proportional to the surface density of the deposit, and estimated that the products of decomposition of $\frac{1}{70}$ mg. of water per square metre would generate an electro-motive force equal to that of a Daniell's cell. It is of the greatest importance to remark that the polarization effects, from which this result is deduced, must have arisen and disappeared in some cases in much less than $\frac{1}{70}$ of a second. The anomalous behavior of the electrolyte with small electrodes is explained by Kohlrausch by taking into account the self-induction of the circuit.

A little consideration will show that the electro-motive force due to this cause always opposes the electro-motive force of polarization, when the current strength is a simple harmonic function of the time. Let i denote the current strength, reckoned positive in a given direction, then according to Kohlrausch's law, the electro-motive force of polarization at time t is $-p\int_0^t idt$, where p is the electro-motive force generated by the passage of a unit of electricity; its value depends on the electrolyte and on the electrode being, *cæteris paribus*, nearly inversely proportional to the surface of the latter. Let n be the number of revolutions of the machine per second, and let $2\tau = \frac{1}{n}$; then we may represent the electro-motive force of the machine at time t by $\frac{k}{\tau}\sin\frac{\pi}{\tau}t$, and the electro-motive force of self-induction by $-q\frac{di}{dt}$, where k and q are constants, the latter being the coefficient of self-induction of the circuit (see Electro-magnetism, p. 72). If w be the whole resistance of the circuit, we may write

$$wi = \frac{k}{\tau}\sin\frac{\pi}{\tau}t - q\frac{di}{dt} - p\int_0^t idt,$$

or

$$q\frac{d^2i}{dt^2} + w\frac{di}{dt} + pi = \frac{k\pi}{\tau^2}\cos\frac{\pi}{\tau}t\,.$$

Neglecting disturbances that die away very soon after starting the machine, we get for the value of i,

$$i = \frac{\frac{k}{\tau}\sin\frac{\pi}{\tau}t}{\sqrt{w^2 + \left(p\frac{\tau}{\pi} - q\frac{\pi}{\tau}\right)^2}},$$

where the origin of time has been thrown back by

$$\frac{\tau}{\pi}\tan^{-1}\frac{1}{w}\left(p\frac{\tau}{\pi} - q\frac{\pi}{\tau}\right).$$

The deflection a of the dynamometer is proportional to $\frac{1}{\tau}\int_0^\tau i^2dt$, and may be written

$$a = \frac{An^2}{w^2 + \left(\frac{p}{2\pi n} - 2\pi nq\right)^2}.$$

Kohlrausch found that this formula completely accounted for all the peculiarities in the behavior of the electrolyte (for the numerical verifications see the papers quoted). We see that the deflection is increased or diminished by the insertion of the electrolyte, according as n is greater or less than $\frac{1}{\pi}\sqrt{\frac{p}{8q}}$, and, if $n = \frac{1}{\pi}\sqrt{\frac{p}{8q}}$, the insertion of the electrolyte makes no difference. Again, if $n = \frac{1}{2\pi}\sqrt{\frac{p}{q}}$, the deflection will be the same as if there were no extra current and no polarization. So that, for any given electromagnetic machine, working at any given speed, a certain electrolytic arrangement can be found, which will exactly eliminate the effect of self-induction, and thereby render the efficiency of the machine a maximum. It is obvious too that, with a given electrolytic cell, the deflection reaches a maximum when

$$n = \frac{p}{2\pi\sqrt{pq - \frac{1}{2}w^2}};$$

this maximum was actually observed by Kohlrausch (*l.c.*).

Test of Ohm's law.

Having due regard to these circumstances, Kohlrausch and Nippoldt found that Ohm's law was applicable to their alternating currents, for electro-motive forces varying from over $\frac{1}{2}$ to under $\frac{1}{74}$ of a Grove's cell. By using the constant current of an iron-copper thermo-electric pair, they found Ohm's law applicable to zinc sulphate with amalgamated zinc electrodes, when the electro-motive force was reduced to $\frac{1}{429000}$ of a Grove's cell.

It is important to remark that the fact that the electrolyte behaves like a metallic conductor through a considerable range of velocities of the sine inductor, is not a conclusive proof that the last trace of polarization has been eliminated.

In fact, let x be the resistance of the electrolyte, W that of the rest of the circuit, and w the metallic resistance that gives the same electro-dynamometer deflection for n revolutions of the inductor per second, then the above formula gives

$$x - w = \frac{2}{2W + x + w}\left(pq - \frac{p^2}{8\pi^2n^2}\right) = \frac{1}{W + w}\left(pq - \frac{p^2}{8\pi^2n^2}\right),$$

---

[1] The advantage gained even with constant currents by increasing the size of the electrodes is, however, appreciable (see below, p. 83).

[2] *Pogg. Ann.*, 1873, and "Jubelbd.," 1874.

since we suppose x very nearly $= w$. If now p be reduced to a very small value, it may happen, especially for tolerably high speeds, that $\frac{p^2}{8\pi^2 n^2}$ is very small compared with pq, in which case $x - w$ will be independent of n through a considerable range of speed, and the electrolyte will be replaceable by a wire whose resistance is less than the real resistance of the electrolyte by a small constant quantity.

The earlier results of Kohlrausch and Nippoldt for sulphuric acid, in which they used 29 cm. electrodes, were affected with an error due to this cause, amounting to about 4 per cent. In the later experiments of Kohlrausch and Grotrian,[1] this error was finally eliminated by "platinizing" the platinum electrodes. Kohlrausch had found that, with "platinized" electrodes of only 1 sq. cm. surface, the polarization of the currents of his sine inductor was insensible; he therefore concluded that, with 25 sq. cm. platinized electrodes, the residual polarization would be finally eliminated. To make quite certain, he instituted three tests, which were carried out on the method used in all the later experiments on this subject.[2]

The Wheatstone's bridge arrangement was adopted. Fig. 26 gives a scheme of the arrangement. The fluid and a rheostat occupy two arms of the bridge, the remaining two contain each 100 Siemens units; A is the fixed and B the suspended coil of the electro-dynamometer, and S the sine inductor.

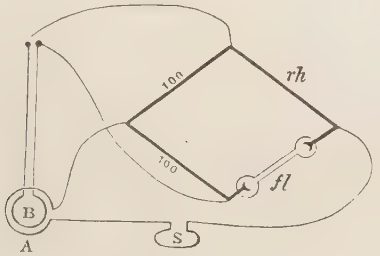

Fig. 26.

In this way, (1) the resistance of a receiver with 25 cm. platinized electrodes was found, when filled first with H_2SO_4 of maximum conductivity, and secondly, with NaCl, the driving weight of the inductor being varied, so as to give speeds of 10 to 100 revolutions. The results, reduced to a common temperature, were, for the H_2SO_4, 141·73, 141·64, 141·52, 141·53, 141·55, and, for the NaCl, ——,[3] 366·27, 366·23, 366·25, 366·21 Siemens units, with the driving weights 5, 7·5, 10, 15, 20 kgr. respectively. (2) The resistance of a solution of zinc sulphate was found, first, in Beetz's manner with constant current and amalgamated zinc electrodes; secondly, using alternating currents and the same electrodes as before; thirdly, with alternating currents and the platinized electrodes; the three results reduced to a common temperature gave 537·49, 537·41, 537·20. The greatest divergence from the mean might have been caused by an error of $\frac{1}{20}$ degree in the temperature measurement. The agreement may therefore be pronounced complete. We think that it must be conceded that the experimental methods just described have solved in a satisfactory manner the problems involved in the determination of electrolytic resistance. We have dwelt on them so long partly because nearly all the information on the subject we possess has been obtained by their means, and partly because they present points of great theoretical interest.

Another method has been employed by Ewing and Macgregor.[4] The electrolyte was inclosed in a narrow tube with wide ends, in which were set platinum electrodes. This arrangement was inserted in a Wheatstone's bridge, and its resistance measured in the usual way. The precautions against polarization consisted in operating with currents of very short duration, sent through the bridge by means of a "rocker" worked by hand; the resistances in the arms of the bridge were also made large, in order to reduce the rate of polarization as much as possible; another essential feature of the method is the use of a "dead-beat" galvanometer with a mirror of very small moment of inertia. The paper of Ewing and Macgregor has formed the subject of a somewhat bitter criticism by Beetz,[5] to which Macgregor has replied.[6]

Battery resistance.

Battery Resistance.—If the electro-motive force and internal resistance of a battery in action were the same, whatever the external resistance, there would be no difficulty in finding the internal resistance by Ohm's method. We have simply to give two different values to the external resistance, and measure the current in the two cases. The electro-motive force does not appear in the ratio of the two current measures; hence, knowing this ratio, we can find the internal resistance. Or we may use an electrometer, and measure the difference of potentials between the two poles of the battery, first, when the external resistance is infinite, secondly, when the external resistance is R. Then, if r be the internal resistance, the ratio of the first electrometer reading to the second is $\frac{R+r}{R}$, by Ohm's law; hence r can be found.

Difficulties in measuring.

Unfortunately, however, the electro-motive force of a battery is *not* independent of the external resistance. In general, when a battery is circuited through a small resistance, its electro-motive force is much smaller than when the external resistance is very great. This arises from the polarization set up by the passage through the battery of its own current, and possibly in some degree from other causes as well. There is also reason to believe that the internal resistance of the battery is a function of the current. This being so, it is clear that a theoretically satisfactory determination of battery resistance cannot be arrived at by such methods as we have described. Since, however, the increase of the electro-motive force is very slow after the external resistance has reached a certain value, and since the alteration of the internal resistance takes some time, we can get in many cases measurements sufficiently accurate for practical purposes. A variety of methods have been devised with this object, and applied mostly to the so-called constant batteries. It must be remembered, however, that there is something indefinite in the term internal resistance, unless the circumstances be given under which it is found. In the method of Von Waltenhofen, the battery is "compensated" by another battery so arranged that no current passes through it; and then this arrangement is slightly altered, so that a very small current passes through the battery. This amounts to finding the internal resistance for very small currents. The method of Beetz also involves the principle of compensation; two batteries are used, but the one whose resistance is to be found is compensator and not compensated. The circuit of the compensator is joined for an instant, and then the compensated battery is thrown in. The assumption in the method is that the electro-motive force is the same in the first instant whether the battery is closed through a resistance R or a resistance R′. The results seem to justify the assumption, and to establish the practical value of the method; but there are clearly limits to its application which it would not be very easy to define. Beetz himself shows that the electro-motive force of a battery is greater when it is compensated than when it is compensating. A similar objection may be urged against the method of Siemens, which again gives good results when properly used. We refer the reader interested in this matter to the sources of information already quoted (see Historical Sketch), and content ourselves with an account of Mance's method, which, although subject to the same objection as all the others, is very convenient for rough purposes, and is much employed in this country.

Mance's method.

Let A, B, C, D be four resistances arranged in circuit, B being the battery whose resistance is required. Insert a galvanometer between $\widehat{AB}$ and $\widehat{CD}$, and a circuit which can be closed and opened by means of a key between $\widehat{AD}$ and $\widehat{BC}$. We thus have an ordinary Wheatstone's bridge, with a key in place of a battery, and a battery in place of the ordinary resistance to be measured. Owing to the presence of the battery, there will be a current through the galvanometer, which will deflect the needle: this deflection is compensated by means of a magnet, and the needle brought back to zero. Then the resistances A,

C, D are arranged *so that the galvanometer is not affected when the key circuit is opened or closed;* when this is so the key and galvanometer circuits are conjugate, and we have $AC-BD=0$, from which we can find B, since A, C, D are known. In practice, however, it is impossible in the great majority of cases to fulfil the direction printed in italics. Suppose for a moment we had arranged the resistances so that $AC-BD$ is very nearly but not quite zero, and suppose we close the key circuit, which had been formerly open, then, since this is not conjugate to the battery circuit, the external resistance opposing the battery is reduced; hence its electro-motive force falls, the *current* through the galvanometer is altered, and the deflection of the needle alters. At the same time there is a current owing to the fact that $AC-BD$ is not exactly zero. These two effects may either conspire or oppose each other. No data, so far as we know, have been obtained which would enable us to tell how quickly this fall in the electro-motive force of any given battery comes on. In practice we see a sudden jerk of the galvanometer, and then a slow swing. The former is due to the deviation of the bridge from balance, and the latter to the alteration of the electro-motive force. It is easy to decide which is which, for the direction of the former can be changed by making $AC-BD$ positive or negative, while the direction of the latter is not affected in this way. This disturbing effect is very great with one-fluid batteries: it would, for instance, be a hopeless undertaking to measure in this way the resistance of a cell of Smee while sending a large current. The effect is not so great with a Daniell's cell, and can be reduced *ad libitum* by introducing metallic resistance into the battery circuit. The effect having been thus reduced within reasonable limits, we operate thus:—Arrange the bridge until the deflection owing to deviation from balance is opposite to that due to the change in the electro-motive force; then, by gradual adjustment, work down the initial jerk to nothing, so that the needle appears to start off on its slow swing without any perceptible struggle. When this state of matters is reached, there is a balance, and $B=\frac{AC}{D}$. Then subtracting from B the resistance put into the battery circuit, we get the resistance of the battery. Of course this does not solve the problem of finding the resistance of any battery sending any current; but we believe that as much can be done in this way as in any other. Various modifications of Mance's method have lately been proposed, but their *practical* advantages over the original method have scarcely as yet been established.

On Resistance in General.

We have drawn no distinction between statistical and dynamical electricity in our application of Ohm's law, and no such essential distinction has ever been proved to exist. In proportion as a body is a good conductor for galvanic electricity, it is a bad insulator for statical electricity. In general, however, bodies which are good enough insulators to retain a charge of statical electricity are so bad conductors that it is with difficulty that we can compare their conductivities by means of the voltaic current. On the other hand, it is difficult by means of statical electricity to compare satisfactorily the conductivities of very good conductors. Determinations of the last-mentioned kind *have*, however, been made by Riess (*vide infra*,—Heating Effects), and the results agree with those obtained by other methods. The insulating power of a substance depends practically to a great extent on the nature of its surface. The dissipation of statical electricity by insulating supports is due, in most cases, almost entirely to the conducting power of a thin surface layer of moisture condensed from the atmosphere, or of some product of chemical decomposition caused by exposure to the air, or of dust or other foreign matter accidentally deposited. As far as high specific resistance is concerned, paraffin, shellac, ebonite, and glass at ordinary temperatures would all be about equally good insulators; but in practice they stand in the order in which we have named them. Paraffin and shellac surpass the other two in their power of preserving for a long time a clean dry surface; ebonite is very good for a time, but ultimately its surface becomes covered with a layer of sulphuric acid, arising from the decomposition of the material; glass, again, is very hygroscopic, although white flint glass, when kept dry by artificial means, is said to be one of the best insulators known.

Order of conductivity.

Metals.

Highest in the order of conductivity stand the metals and their alloys. In this class of bodies the passage of the electric current is unattended by chemical decomposition, and the conductivity decreases as the temperature increases. Along with the metals may be ranked a few other bodies, which have anomalous conductivity, but are not decomposed; such as graphite, red phosphorus, chloride and oxide of lead under the melting-point, various sulphides and selenides, tellurium, and selenium. In the great majority of the bodies included in this supplementary class the conductivity increases with the temperature; the last two present several anomalies, to which we shall refer farther on.

Electrolytes.

A second class of bodies is formed by those which are decomposed by the electric current. The specific conductivity of these is much lower than that of the metals, and it increases when the temperature is raised. To this class belong, when in solution or in the melted state, most simple binary compounds composed of equal equivalents of two elements, and compounds derived from these by "double decomposition" (see, however, art. ELECTROLYSIS); also some sulphides which have an anomalous conductivity, and glass and some bodies like it, which in the melted state and in the soft state preceding fusion conduct as electrolytes.

Non-conductors.

Non-conductors, on the other hand, are:—All gases and vapors, whether at ordinary pressures or in what is called a vacuum, diamond, sulphur, amorphous phosphorus, amorphous selenium, fluid chlorine, bromine, solid and melted iodine, bichloride and biniodide of tin, sulphuric anhydride, solid silicic acid, oxide of iron, oxide of tin; most compounds that are not binary, that is, do not consist of an equal number of equivalents of two components, *e.g.*, many organic compounds—etheric oils, resins, wood fibre, caoutchouc; also "binary compounds" in the solid state. To these may be added *pure* water, *pure* hydrochloric acid, etc., which are very bad conductors, if not absolute non-conductors.

Before leaving this part of our subject, it will be interesting to throw together a few of the general principles that have been arrived at, and to give a few numerical results, which will convey to the reader an idea of the position of the different classes of bodies in the scale of conducting power. For further details we refer to Wiedemann's *Galvanismus.*

Specific resistance and temperature coefficient of metals.

Metals.—(1.) It was remarked by Forbes that the order of conductivity is the same for electricity as for heat. The measurements of Wiedemann and Franz have established that the ratio of the conductivities for heat and for electricity is very nearly constant, not only for pure metals, but also for alloys. (See Wiedmann's *Galvanismus*, bd. i. § 194.)

(2.) The conductivity of the pure metals decreases as the temperature rises from 0° to 100° C., the rate of decrease becoming smaller towards the upper limit. Matthiessen expresses the conductivity by the formula $k=k_0(1-\alpha\theta+\beta\theta^2)$, where k_0 denotes the conductivity at 0° C., θ the temperature, and α and β constants. He found that α and β had nearly the same value for all pure metals in the solid state, with the exception of thallium and iron, and gives as the mean values for pure metals $\alpha=0{\cdot}00376470$, $\beta=0{\cdot}0000083402$. The values for iron are $\alpha=0{\cdot}0051182$, $\beta=0{\cdot}000012915$; for mercury, $\alpha={\cdot}0007443$, $\beta=0{\cdot}0000008263$. Although there can be no doubt about the general agreement in the formulæ for the different pure metals, yet the actual formula arrived at is purely empirical and must be used only between 0° and 100° C. If we carried its application beyond, it would give a minimum conductivity for pure metals about 300° C. The direct experiments of Müller and Siemens give no indication of such a minimum. The latter represents the results of his experiments (extending in some cases as far as 1000° C.) by means of the formula $r=\alpha\sqrt{T}+\beta T-\gamma$, where r is the specific resistance, T the absolute temperature, α, β, γ constants. Relying on a formula of this kind for platinum, Siemens has constructed a pyrometer for determining the temperature of furnaces by means of resistance measurements.

(3.) As we have seen, the specific resistance of pure metals goes on increasing continuously as the temperature rises. At the melting-point there is a sudden rise in the resistance, and after that the resistance goes on increasing with a smaller temperature coefficient than before. This is in accordance with the fact, that both the specific conductivity and temperature coefficient of mercury are smaller than those of the other metals in the solid state. Bismuth and antimony are exceptions to this rule, in that there is a sudden decrease of resistance at the melting-point. According to the results of L. de la Rive, the resistance of metals in general is about doubled in passing the melting-point. We should therefore expect the specific conductivity of frozen mercury to be about 3·31, that of silver being 100.

Alloys.

Alloys.—(1.) Matthiessen found that the metals could be divided into two classes, according to the conducting properties of their alloys:

- *a*. Lead, Tin, Cadmium, and Zinc.
- *β*. Most of the other metals—Bismuth, Antimony, Platinum, Palladium, Iron, Aluminium, Sodium, Gold, Copper, Silver.

Let v, v' be the volumes, s, s' the specific gravities, k, k' the conductivities of the two components of any alloy; and let $\bar{s} = \frac{vs + v's'}{v + v'}$, and $\bar{k} = \frac{vk + v'k'}{v + v'}$, be called the mean specific gravity and mean conductivity of the alloy. Then alloys of any one metal of class *a*, with any other of the same class, have very nearly the mean specific gravity and conductivity calculated by the above formulæ.

Alloys of a metal *a* with a metal *β* have specific gravity and conductivity always less than the mean. If a metal *a* is alloyed with a considerable percentage of *β*, the conductivity is not much altered, but if a metal *β* be alloyed with even a very small quantity of *a*, the conductivity is greatly reduced.

Alloys of the metals *β* among themselves have in general a conductivity much inferior to that of either component. The conductivity remains constant through a considerable range of percentage, but rises very quickly as the percentage of either metal approaches 100. This property is very marked in an alloy of gold and silver. Matthiessen recommended an alloy of two parts by weight of gold to one of silver for the reproduction of the standard of resistance. The resistance of such an alloy would be very slightly affected by small variations in its composition.

Mercury, and melted metals generally, are not subject to the foregoing laws. A very small percentage of another even worse conducting metal raises the conductivity of mercury, but the addition of larger quantities of the foreign metal lowers the conductivity.

(2.) The formulæ for the temperature variation for alloys of the metals *a* among themselves agree very closely with the mean formulæ calculated from the volume percentages.

If P denotes the fraction of itself by which the conductivity at 0° exceeds that at 100° for an average pure metal (P = 0·29307), and $\bar{P}$ the same fraction, observed in the case of any alloy for which the observed and mean or calculated conductivities at 0° and 100° are k_0, k_{100}, and $\bar{k}_0$, $\bar{k}_{100}$,—then, according to Matthiessen, the following relation holds for alloys of metals *a* among themselves, and metals *β* among themselves :—

$$P : \bar{P} : : k_{100} : \bar{k}_{100},$$

or, which is the same thing, R_0, etc., denoting resistances,

$$R_{100} - R_0 = \bar{R}_{100} - \bar{R}_0.$$

For alloys of *a* with *β*, the observed value of P is in general greater than that calculated by this formula.

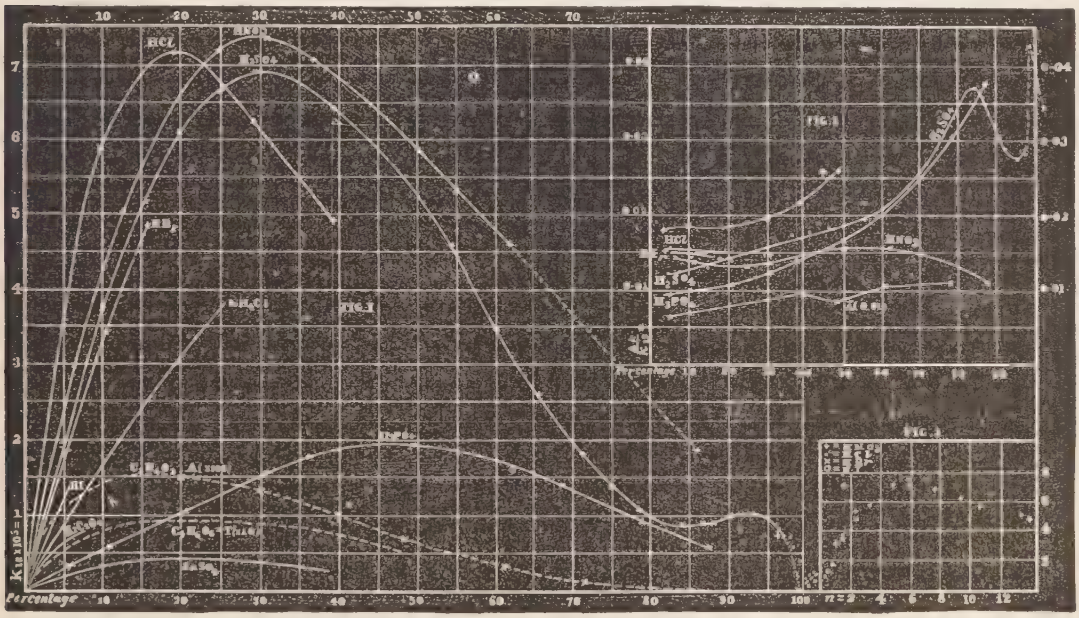

Diagram illustrating Electrical Conductivity.

Effect of physical condition.

Other Physical Conditions affecting the Resistance of Solid Bodies.—Besides temperature, a variety of other circumstances affect the specific resistance of metals. As a general rule, metals are worse conductors in the hard than in the soft state. Tempering steel increases its resistance considerably, but subsequent heating and gradual cooling reduce the resistance again. The resistance of a wire stretched by a weight is increased more than can be accounted for by the mere decrease of the section.[1] Winding on a bobbin has the same effect. The finer a metal is drawn into wire, the greater is its specific resistance in the case of iron, the smaller in the case of copper. Magnetization has also in certain cases been found to affect the resistance. These effects were studied by Sir William Thomson; the results of his researches are given in his Bakerian Lecture, *Phil. Trans.*, 1856. The experiments are very instructive, and many of them well worth repeating now that we have more delicate apparatus. The most curious case of alteration of resistance is that of tellurium and selenium. We have already mentioned that selenium in the amorphous state is a non-conductor. After continued heating it passes into the crystalline state and conducts. Sale found[2] that the conductivity of this crystalline form of selenium is greatly affected by light, and that, too, differently by light of different colors. Prof. W. G. Adams[3] has lately made a series of experiments on the subject, and concludes that there is an action of light which varies as the square root of the illuminating power, and is distinct from any heating effect. He found the resistance of selenium in one case diminished by a fifth when it was exposed to the light of a certain paraffin lamp; the change in tellurium under similar circumstances was $\frac{1}{300}$th. He found that the passage of a strong current through selenium sets up a kind of polarization, which opposes a current in the same direction as that which produced it, and aids a current in the opposite direction. This led him to suspect that the action of light might of itself start a current in the selenium, and he found that under certain circumstances this is the case.

Specific resistance and temperature coefficient of electrolytes.

Fluids.—The verification by the experiments of Kohlrausch and Nippoldt of Ohm's law for electrolytes, through a wide range of electro-motive force, has greatly increased the interest of all data relating to the resistance of this class of conductors. We have no difficulty in working with electrolytes whose composition and physical state is perfectly definite, a thing next to impossible in the case of solids. Hence the resistance of an electrolyte has, far beyond the resistance of a solid metal, a value as datum for physical speculations concerning the ultimate properties of matter, which underlie Ohm's law. We refer the reader to Wiedemann's *Galvanismus* for an account of the earlier results in this department of Pouillet, Hankel, Becquerel, Horsford, Wiedemann, Becker, Lenz, and Saweljew. We recommend to his notice particularly the careful experiments of Beetz on zinc sulphate (his temperature determinations are the most extensive of the kind), also the researches of Paalzow, who examined the conductivity of various mixtures of two solutions, the conductivities of which had been separately determined. He finds that if R and R′ be the resistances of the components, the resistance of the mixture is not $\frac{RR'}{R+R'}$; so that the current is not divided between the liquids as if they were metals in multiple arc; nor is it the mean of R and R′, but it lies nearer the smaller of the two. A similar result was arrived at by Ewing and Macgregor.[1]

---

[1] For recent experiments on this subject see *Proc. R. S.*, Dec., 1876, and June, 1877. Authorities for some of the other facts stated will be found in Wiedemann, i. § 207.

[3] *Proc. R. S.*, vols. xxiii., xxiv., xxv.

Kohlrausch and Grotrian[2] have made the most recent as well as the most extensive investigations; and we shall best describe the present state of scientific knowledge on this subject by giving an analysis of their results and conclusions. Their experiments deal with the chlorides of the metals of the alkalies and alkaline earths. Kohlrausch has also examined a number of the commoner acids. For convenience we have transcribed the diagram given by Kohlrausch, which embodies certain of the results obtained by himself and Grotrian. Fig. 1 of the diagram gives the conductivities[3] (k_{18}) at 18° C.; the ordinates represent $k_{18} \times 10^5$, except for acetic and tartaric acid, where they represent $k_{18} \times 10^7$ and $k_{18} \times 10^6$ respectively, the abscissæ represent percentages by weight in the solution of HCl, H_2SO_4, NH_4Cl, etc. In fig. 2 the values of the temperature coefficient $\left(\frac{\Delta k}{k_{18}}\right)$ for 18° C. are given by the ordinates, the abscissæ being percentages as before. For convenience of drawing the coefficient of acetic acid is decreased by 0·01.

The curves which appear in the diagram include all the distinct varieties; and it will be seen that in all cases the conductivity varies continuously with the concentration, an approach to zero for infinitely weak solutions being indicated in all cases. The chlorides may be divided into two classes. (1.) $CaCl_2$ and $MgCl_2$ reach maximum conductivities 1968×10^{-8}, 1310×10^{-8}, at 18° C. for percentages 24 and 19·8 respectively, in each case short of saturation. LiCl probably does the same, and NaCl appears to reach a maximum between 23·9 p.c. and its saturation percentage 26·5. (2.) KCl, NH_4Cl, $SrCl_2$, and $BaCl_2$ increase in conducting power up to the point of saturation.

Taking the best conducting solutions, the order of conductivities is NH_4Cl, KCl, NaCl, LiCl, $CaCl_2$, $SrCl_2$, $BaCl_2$, $MgCl_2$, the alkaline chlorides heading the list. A 25 p.c. solution of NH_4Cl is in fact half as good a conductor as the best acid solution known.

It was found that, if the conductivity for small percentages be represented by $k = \kappa p - \kappa' p^2$, so that κ may be called *the specific conductivity in watery solutions*, then κ varies inversely as the specific gravity, that is, directly as the "specific volume."

The temperature coefficients for the chlorides are very nearly independent of the temperature. There is a slight increase for higher temperatures, which is most marked in the case of highly concentrated and viscous solutions of $CaCl_2$, $MgCl_2$.

For weak solutions the coefficients are all very nearly equal; at 18° C. the extreme value for 5 p.c. solutions lies between $\frac{1}{46}$ (for LiCl) and $\frac{1}{52}$ (for NH_4Cl). There is a tendency, as seen by the curves, to a value $\frac{1}{45}$, or ·022 for very weak solutions. It will be noticed (see table below) that this coefficient is much larger than ·0039, which is about the corresponding number for a pure metal.

When the percentage is increased from five upwards, the temperature coefficient for 18° C. decreases at first for all the chlorides; it reaches a minimum for NaCl, $CaCl_2$, $MgCl_2$, which belong to class (1); but there is no minimum for KCl, NH_4Cl, $BaCl_2$, which belong to class (2), and have no maximum conductivity.

The acids investigated were nitric, hydrochloric, sulphuric, phosphoric, oxalic, tartaric, and acetic. In every case, except that of oxalic acid, a maximum conductivity was obtained. The order in which we have named the acids is that of the conductivity of the best conducting solutions at 18° C.; for the first three we have respectively $k_{18}10^8 = 7330$, 7174, 6914, the corresponding percentages being 29·7, 18·3, 30·4, so that the maxima are very nearly equal, and the maximum percentages not far apart. The curve for sulphuric acid is exceedingly remarkable. Between 0 and 100 p.c. of H_2SO_4, it shows two maxima. The first minimum occurs at the percentage corresponding to the hydrate $H_2SO_4 + H_2O$. The conductivity corresponding to H_2SO_4 is also a minimum; for when SO_3 is added, causing supersaturation, the conductivity again increases, there must therefore be *at least* one more maximum, since melted SO_3 is a non-nonductor. There is no peculiarity in the curve corresponding to the hydrate $2H_2O + H_2SO_4$, which is distinguished from $H_2O + H_2SO_4$, in not being crystallizable. A striking similarity in the case of sulphuric and acetic acid is remarked between the curves of *resistance* and of *solidification temperature;* wherever the latter is high, the former is so also; there is a maximum in both cases for $H_2O + H_2SO_4$, and for H_2SO_4, and a minimum in both cases near 92·5 p.c.; the other minima do not agree so well.

A remarkable relation is given, which appears to connect the resistance of the monobasic acids HCl, HBr, HI, and HNO_3. If any percentage be multiplied by the specific gravity of the solution, and divided by the molecular weight of the acid, the result is the number of molecules (n) in unit of volume of the solution. On forming a table of resistances with n for argument, it was found that for solutions with the same n, whether of HCl, HBr, HI, or HNO_3, the conductivity is the same. This appears very clearly from the dotted curve in fig. 3 of the diagram, calculated from the different acids, the regularity of the curve, and in parts the coincidences, are very marked. This result may be stated thus:—*In solutions containing an equal number of molecules, whether of* HNO_3, HCl, HBr, *or* HI, *the components of electrolysis under equal electro-motive forces pass in opposite directions with equal relative velocities.*[4]

The temperature coefficients for the four monobasic acids are nearly equal, and nearly independent of the concentration. The same increase of temperature coefficient with increase of concentration as was noticed in the case of viscous chloride solutions appears also in the viscous acid solutions of phosphoric, tartaric, and sulphuric acid. It is also found that where the conductivity is a minimum, the temperature coefficient is correspondingly great; so that, with increasing temperature the maxima and minima tend to get smoothed out. It appears also that the proximity of the maxima for H_2SO_4, HNO_3, HCl, becomes more marked as the temperature rises.

The existence of the maxima in most cases, and of the minima in the sulphuric acid curve, led Kohlrausch to suggest the principle that no stable chemical compound in a pure state is a conductor, and that mixture of at least two such compounds is necessary for conduction. He mentions many instances of this principle, *e.g.*, water, sulphurous acid, carbonic acid, acetic acid, melted boracic acid, chromic acid, anhydrous SO_3, etc. In a recent paper[5] he gives some very interesting results concerning the conductivity of pure water and other bad conductors. The lowest conductivity he got for water was 71 ($Hg = 10^{12}$). This was after careful purification and repeated distillation in glass, and finally in platinum vessels. After standing under a glass bell jar for 4·3. 20, 78, and 1060 hours, the water rose in conductivity from 78 to 133, 350, 850, and 3000 respectively. He calculates that, if pure water were a non-conductor, the presence of 0·2 mgr. per litre of HCl would be sufficient to account for the observed conductivity. He also found conductivities for $SnCl_4$ (<) 200, alcohol (commercial distilled) 30, acetic acid (glacial melted) 4, ether (<) ·8. Among recent researches of interest may be mentioned Braun's attempt[6] to measure the conductivity of melted salts, and Grotrian's[7] on the relation between the viscosity and the electric conductivity of electrolytes. For the speculations of Kohlrausch, Hankel, Beetz, Wiedemann, and Quincke on the ultimate nature of electrolytic resistance, see the papers of the first-mentioned, or Wiedemann's *Galvanismus*, Bd. i. § 434 *sqq.*

Gases.

Gases.—We are not aware that any experiments have hitherto established that any gas or vapor at ordinary temperature and pressure is a conductor. Boltzmann[8] has arrived at the negative result that air at ordinary temperature and pressure must have a specific resistance *at least* 10^{26} times that of copper. Sir William Thomson has, we believe, arrived at a similar result for steam; and recent experiments by Prof. Maxwell[9] on air, steam, mercury, and sodium vapor (at high temperatures) have led him to a similar negative conclusion. It was found, however, that the heated air from a Bunsen's burner conducts remarkably well.[10] The so-called unipolar conductivity of flames presents many anomalies, which have been examined by various experimenters. For the literature see F. Braun, *Pogg. Ann.*, 1875.

It would appear, therefore, that the loss of electricity from insulated conductors at moderate potentials, observed by Coulomb and Riess, cannot be due to conduction or convection by the air, but must arise almost wholly from the insulating supports. Warburg, who has experimented much on this subject, appears to be of the same opinion (*vide* Boltzmann, *l.c.* p. 415).

[1] *Trans. R.S.E.*, 1873.

[2] *Pogg. Ann.*, cliv., 1875, and clix., 1876.

[3] Mercury is the standard.

[4] A similar law might be stated for the chlorides, but it holds only for very weak solutions.

[5] The residual conductivity he would attribute to residual impurities, or as in the case of H_2SO_4 and melted salts, to dissociation, whereby the solution becomes in reality a mixture of different compounds.—*Pogg. Ann.*, clviii., 1876.

[6] *Pogg. Ann.*, cliv., 1875.

[7] *Pogg. Ann.*, clvii., 1876; clx., 1877.

[8] *Pogg. Ann.*, clv., 1875.

[9] Unpublished results.

[10] Herwig (*Pogg. Ann.*, 1874) has recently concluded from some experiments that Hg vapor *does* conduct in a certain anomalous way. His experiments were complicated by the conductivity of the glass tubes containing the heated vapor; steps were taken, however, to eliminate this. Considerable doubt hangs over the whole subject.

Varley has lately investigated the passage of the current of a large number of Daniell's cells through a Geissler's (hydrogen?) tube. He found that it required 323 cells to *start* the current, but that it once it was started it could be maintained by 308 cells; the current which flowed was proportional to the excess of the number of cells over 304. Thus, for $317 = 304 + 13$ the current was proportional to $25\frac{1}{2}$, for $330 = 304 + 26$ it was proportional to 51. Accordingly, if E_0 be a constant, and R another constant (the resistance of the gas?) we get for the electro-motive force E, required to send a current I, $E = E_0 + RI$. E_0 is analogous to the electro-motive force of polarization. For further details about the resistance of di-electrics we refer the reader to Maxwell's *Electricity and Magnetism*, vol. i. § 366 *sqq.*

General table.

The following table will give an idea of the conducting power of different bodies; *r* denotes the specific resistance in C.G.S. units (to reduce to ohms divide by 10^9); *a* is the percentage of itself that *r* increases in the case of metals and decreases in the case of electrolytes per deg. C.; *t* is the temperature at which *r* is given.

	t	*r*	*a*

On the Passage of Electricity through Insulators.

Disruptive discharge.

Hitherto we have divided bodies into *conductors*, through which electricity passes under the influence of any electro-motive force, however small, and *non-conductors* or *insulators*, through which electricity will not pass, no matter how great the urging force. In practice, however, when the value of the electro-motive force reaches a certain limit, electricity *does* pass through a non-conductor. A discharge of electricity taking place suddenly in this way through a non-conductor is called a "*disruptive discharge.*" The power of a non-conductor to resist up to a certain limit the passage of electricity through it has been called its *di-electric strength*. The di-electric strength of any medium is greater the greater the electro-motive force it will stand, when placed say between two parallel metal plates arranged in a given way, before it is broken through by the disruptive discharge. We shall by and by attach a definite quantitative signification to the term, but the general notion will be sufficient for the present.

Although it may be found when both phenomena have been more fully analyzed, that conductive and disruptive discharge are really two different aspects of one and the same phenomenon, yet for the experimenter they are two distinct things, which must not be confounded.

This would be the place to set forth the quantitative relations which regulate the electro-motive force required to produce disruptive discharge, the quantity of electricity that passes under given circumstances, and the di-electric strength of different media; in fact, to lay down for disruptive discharge a law corresponding to the law of Ohm for metallic and electrolytic conduction. The present state of electrical science, however, does not permit us to do this in a satisfactory manner. Experiment has not as yet led to a single dominant principle, like Ohm's law, which will account for all the phenomena of disruptive discharge. The best theory of the subject is Faraday's, which will be gone into under "*disruptive discharge in gases.*" Observation and experiment, on the other hand, have been occupied for the most part with the various transformations of energy which accompany the disruptive discharge. We prefer, therefore, to discuss the whole matter under the single head "disruptive discharge."

TRANSFORMATIONS OF ENERGY ACCOMPANYING THE ELECTRIC CURRENT.

Under this head we propose to discuss (to use a word of Rankine's) the energetics of electricity. It may be objected that this heading might have been put over a good deal of what has gone before, and we shall, for convenience, treat certain matters under it which, in a strictly logical division, would have found a place elsewhere. If we had formed a definite conception of what we call electricity—had, for instance, assumed that it is a material fluid, having inertia like other fluids, then no doubt the energetics of the subject could have been much extended. As it is, we think that advantage is to be gained by associating in our minds the experimental laws which we are now to arrange under the above heading.

We shall consider (1) the heat developed in metallic and electrolytic conduction, and at the junctions in heterogeneous circuits; (2) the mechanical, sound, heat, and particularly light effects accompanying disruptive discharge; (3) the energy of magnetized iron and steel, and of electric currents in the neighborhood of the electric current (electro-magnetism); (4) the energy of the electro-tonic state, or electro-kinetic energy (magneto-electric induction). In this list ought to be included the potential energy of chemical separation, which would come under the head of electrolysis. At present, however, electrolysis is quite as much a chemical as an electrical subject, and it has been found convenient to treat it in a separate article (see ELECTROLYSIS). Some points in connection with it have already been touched upon, and a few more will come up in (5), which treats of sources of electro-motive force, and deals with the question, whence comes the energy which is evolved in the voltaic circuit? a question the answer to which is for the most part experimental and practical—the only one, in fact, that the state of electrical science permits us to give.

Heating Effects.

Development of heat in circuit.

It is easy to show, by a variety of simple experiments, that a current of electricity heats a conductor through which it passes. In the case of moderately strong currents the heat developed is perceptible to the touch; the wire may, in the case of very strong currents, be raised to a white heat; it may melt, and even be volatilized. In the case of very weak currents, the heating effect may be demonstrated by passing the current through the spiral of a delicate Breguet's thermometer. We find, when we examine the experimental data on the subject, that heating effects may be conveniently divided into two distinct classes. In the first of these the fundamental law is that the development of heat in any part of a linear circuit varies as the resistance of that part multiplied by the *square* of the current. In the second class the development of heat varies as the *first power* of the current. The heating effects of the first class are obviously independent of the direction of the current, and are irreversible; and the more we examine them the more they appear to correspond to the loss of energy by the frictional generation of heat in ordinary machines. In the language of the dynamical theory of heat, the part of the energy of the electric current which disappears in this way is said to be dissipated. The effects of the second class change their sign when the direction of the current is changed; so that, if anywhere there was evolution of heat when the current flows in one direction, then, when the current is reversed, there will be absorption of heat to an equal extent. We shall find that we have great reason to believe that such effects are strictly reversible.[1] In order to get a satisfactory foundation for the simple theoretical views which we have thus indicated, it is essential to be able to separate the two classes of effects. Now, this is possible to a very great extent even in practice. The effects of the first class increase much more rapidly with the strength of the current than those of the second, so that, by sufficiently increasing the current, we can make the effects of the second class as small a fraction of the whole heating effect as we please; while, on the other hand, by sufficiently decreasing the current, the preponderance of the second class may be increased to any desired extent. We shall in what follows suppose the two classes of effects separated in this way.

Discharge of Statical Electricity.—One of the earliest attempts to study the heating effects of the electric discharge

---

[1] That is, in the thermo-dynamic sense.

Heating effects of discharge.

was made by Kinnersley. He constructed a thermo-electrometer, which consisted of a closed glass vessel, in which were fixed two metal balls communicating with electrodes outside the vessel. The bottom of the vessel was filled with a little colored fluid, which communicated with a tube having a vertical arm rising outside the vessel. When a spark passed between the balls, the heat developed caused the air to expand and force the liquid into the vertical tube, the rise of level in which indicated the degree of expansion, and, by inference, the amount of heat developed in the spark.

Experiments of Harris.

Sir Wm. Snow Harris[1] revived this instrument of Kinnersley's, and improved it by stretching a fine wire between the terminals inside the vessel, so that the heat measured was now that evolved in a metallic conductor.

With this improved instrument he made a number of valuable experiments on the heating of wires by the discharge of a Leyden battery, whose charge was measured by a Lane's electrometer. Assuming that the heat developed varies inversely as the conductivity of the wire (which is not the case), he arranged the metals in a series which agrees with that given later by Riess, although the numbers given do not properly represent the conductivities owing to the erroneous assumption on which they are deduced. Harris observed that the specific conductivity of alloys is often less than that of either metal, and that a very small admixture of another metal considerably reduces the conductivity of pure copper. He also arrived at the result that the amount of heat developed in a wire varies as the quantity of electricity which passes in the discharge, but seems to have concluded that the amount of battery surface used had no effect.[2]

Riess. Thermo-electrometer.

Riess made two very important improvements on the thermo-electrometer by substituting spirals for the straight wire of Harris, and by inclining the tube containing the liquid so as to be nearly horizontal. The sensibility of the instrument was thus greatly increased. Riess took up the whole question of the heating of wires, and investigated it thoroughly.

The actual instrument which he used is represented in figure 27 (taken from his *Reibungselectricität*). It consists of a glass tube of narrow bore, 16 to 17 inches long, to which is blown a glass globe 3 to 4 inches in diameter. This tube is partially filled with some colored fluid which confines the air in the globe; a wide reservoir at the other end of the tube allows the fluid to accumulate without sensible change of level. The stand of the instrument consists of two pieces hinged together, so that the tube can be placed at a small inclination to the horizon. The rest of the instrument will be understood from the figure. Details concerning the manipulation will be found in the *Reibungselectricität*, Bd. i. § 410. When the fine wire is heated by a current of electricity, the heat developed is divided between the wire and the air; the expansion very quickly reaches a maximum, and the level of the liquid in the fine tube becomes stationary for a moment. If m be the number of scale divisions between its original and final positions, we have (see Riess, *l.c.*, or Mascart, t. i. § 325)

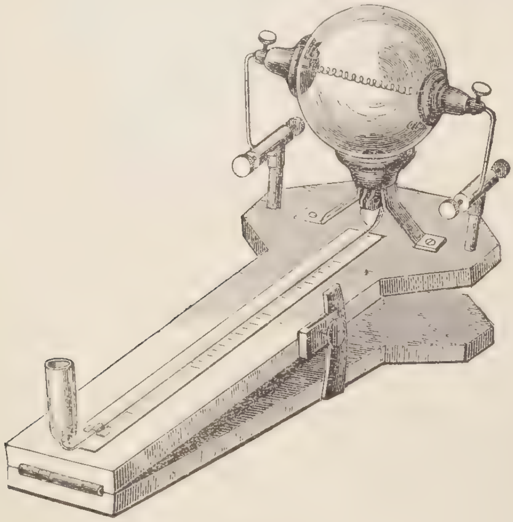

Fig. 27.

$$T = mA\left(1 + \frac{B}{CW}\right), \text{ and } H = mA(CW + B), \quad . \quad . \quad . \quad (1)$$

where T denotes the amount by which the temperature of the wire would have risen had no heat left it, and H the whole amount of heat developed by the current. C and W are the mean specific heat and weight of the wire, and A and B constants, which depend on the make of the instrument, and on the initial temperature and pressure of the air.

A very convenient form of thermo-electrometer, called the *thermometre inscripteur*, has been used by Mascart (*l.c.*). The alterations of pressure are registered automatically on a revolving drum, after the manner of the pulse-registering instrument of Marey. One advantage of this instrument is that it gives a representation of the course of the temperature in the apparatus.

In most of his experiments Riess used batteries of Leyden jars. The jars were all as nearly as possible alike, and the inner armatures were in general connected together. The quantity of electricity given to the battery was measured by means of a Lane's jar, the balls of which were placed at a distance of about a line apart. The battery was then discharged through the thermo-electrometer along with any external circuit connected with it.

General considerations.

It is of great importance in such experiments as we are now describing to examine what happens at the place where the circuit is closed. This closure is effected by bringing two metallic balls into contact. But before contact is reached, a spark passes in which sound, light, and heat are given forth,—in a word, energy evolved. When the resistance of the circuit is small, this spark passes at a considerable distance, and is very intense, no matter how quickly the conductors are brought together. The energy consumed in this case is a considerable fraction of the whole energy given out by the discharge. If, however, the resistance of the circuit through which the discharge takes place be considerable, the electricity takes longer to accumulate sufficiently to raise the electro-motive force between the balls to the discharging limit. We may, therefore, by operating quickly, get the balls very nearly in contact before the spark passes. In this case the spark is much less intense, and the fraction of the whole energy which appears in it is very small. Riess made some very valuable experiments on this point. He arranged an air-break in the circuit of the thermo-electrometer, which he could widen or narrow at pleasure, and discharged his batteries through this circuit in the usual way. He found that as the gap is widened the amount of heating in the thermometer is at first increased, but after a certain length of break is attained it decreases again. It must be remembered that we have now two air breaks in our circuit of discharges, the discharging break and the inserted break. One effect of the inserted break is to diminish the intensity of the spark at the discharging break, and cause a decrease of the energy which appears there. On the other hand it makes the discharge of the battery *incomplete*, so that part of the potential energy is not exhausted. It is very likely to the opposition of these two effects that the peculiarity observed by Riess is due. Mascart has observed a similar phenomenon in disruptive discharge through oil of turpentine. At all events Riess showed that, when the inserted break was not longer than $\frac{2}{10}$ths of a line, the heating in the thermometer was the same as when there was no break at all. Hence, if we make the resistance of our circuit so great that the spark at the discharger is not longer than $\frac{2}{10}$ths of a line, the energy consumed there may be neglected.

General law.

The resistance of the connections belonging to the battery and the thermometer were always very small compared with that of the thermometer wire, and the wire, if any, inserted outside the thermometer; so that, if the resistances of these be R and S, the resistance of the whole circuit may be taken to be R+S. The law to which the experiments of Riess led can be expressed by means of the formula

$$H = \frac{S}{R+S}Q, \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where Q is the amount of electric potential energy which has disappeared, and H the amount of heat (measured by its dynamical equivalent) developed in the wire of the thermometer, whose resistance is S.

---

[1] *Phil. Trans.*, 1827.

[2] *Phil. Trans.*, 1834.

In the case of the complete discharge of a battery of n jars, each of capacity C, if q be the whole charge, we get immediately, from (48) of Mathematical Theory (p. 33),

$$Q=\frac{q^2}{2Cn}, \text{ and}$$

$$H=\frac{S}{R+S}\cdot\frac{q^2}{2Cn}. \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Hence, if we keep the thermometer and inserted wires the same, the thermometer indications will be proportional to $\frac{q^2}{n}$, or in words—*the heat evolved in the whole or in any given part of the circuit is proportional to the square of the battery charge directly, and to the number of jars* (i.e., *to the battery surface*) *inversely.*

If the thermometer wire remain the same, while the length, section, and material of the inserted wire are varied, then, r being the specific resistance, l the length, and ρ the diameter of that wire, $R=\frac{4rl}{\pi\rho^2}$. Then, according to (3), the heat developed in the thermometer is given by

$$H=\frac{A}{1+B\frac{rl}{\rho^2}}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where A and B are constants.

If, again, we use two wires of the same material of lengths l and l' and diameters ρ and ρ', and make two observations with these for inserted and thermometer wires respectively and *vice versâ*, then, if H_1 and H_2 be the heat evolved in the two cases,

$$\frac{H_1}{H_2}=\frac{l'\rho^2}{l\rho'^2}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

since R + S is the same in the two cases.

When the discharge is not complete, we have only to substitute for Q in (3) the appropriate expression for the exhaustion of the electric potential energy. Similarly we may find the heating effect caused by the discharge of a battery of jars arranged in series and charged by cascade in Franklin's manner (p. 33). If we discharge through a multiple arc, we may assume that the discharge divides itself between the branches in the ratio of the conductivities, so that the conductivity of the whole arc is the sum of the conductivities of its parallel branches. On these principles it is easy to calculate the heat generated in the whole circuit or in any branch of the arc.

All the cases we have alluded to were treated experimentally by Riess, and satisfactory agreement with formula (2) established in every case.

Comparison of conductivities.

By means of formula (4) he compared the specific conductivities of a variety of metals. A and B were determined, and a standard wire of platinum of given length kept in the thermometer; the wires to be compared with it were inserted in the outside circuit, and the heating in the thermometer observed. From the result the specific conductivity (in terms of platinum) of the wires could be calculated, their dimensions being known. The results agree very well with those got by other means.[1]

Heating effects of constant current.

Heating by Constant Current.—The heating effect of the current furnished by a voltaic battery was recognized as a distinct and often very remarkable phenomenon for a considerable time before any definite quantitative law was established regarding it. Davy[2] experimented on wires of the same dimensions but of different materials, and found that the metals could be arranged in the following order:—silver, copper, lead, gold, zinc, tin, platinum, palladium, iron,—those standing nearer the beginning of the list being less heated by a given current than those nearer the end.

Joule's law. Metals.

Joule[3] was the first, however, to establish a definite law connecting the amount of heat evolved per second with the current strength and the resistance of the wire. He wound the wire in which the heat generated was to be measured round a glass tube which was immersed in a calorimeter. The resistance of the water is so great that we may assume without sensible error that the whole of the current passes through the wire. The temperature of the water was determined by means of a mercury thermometer immersed in the calorimeter. The amount of heat developed in the wire per second could then be found by the usual calorimetric methods. The strength of the current was measured by means of a galvanometer inserted in the battery circuit along with the wire. By experiments of this kind Joule established that *the amount of heat generated in a given time varies directly as the product of the resistance of the wire into the square of the strength of the current.* So that, if we choose our units properly, we may write

$$H = RI^2t, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where R is the resistance of the wire, I the strength of the current, and H the quantity of heat generated in time t.

The experments of Joule were repeated with increased precautions against error by Becquerel,[4] Lenz,[5] and Botto. Becquerel allowed the wire to disengage heat till the calorimeter reached such a temperature that the loss of heat by radiation and convection, etc., was just equal to the gain from the wire, so that the temperature became stationary. The current was then stopped, and the loss of heat per second found by observing the fall of temperature in the calorimeter. Botto used an ice calorimeter. Lenz[6] made a series of very careful experiments with a calorimeter, in which the liquid used was alcohol, which is a much worse conductor than water. He first cooled his apparatus a few degrees below the temperature of the surrounding air, and then allowed the current to generate heat in the wire till the temperature of the whole calorimeter (which was kept uniform by agitation) had risen to an equal number of degrees above the temperature of the air. The current was then stopped, and the time t which it had flowed noted. According to Joule's law, tRI^2 ought to be constant, and it was found to be so very nearly. A very convenient instrument for demonstrating and measuring the heat generated by the electric current in a wire is the galvano-thermometer of Poggendorff, which consists simply of an alcohol thermometer with a large bulb, into which is let a spiral of fine wire. The heat generated is deduced from the expansion of the alcohol, which is measured by means of a scale fastened to the stem of the thermometer. The value of the graduations is found by comparison with an ordinary thermometer. The thermo-electrometer of Riess might also be used in a similar way.

Electrolytes.

Heating in Electrolytes.—Joule's law applies also to electrolytes. The phenomenon, however, is not so simple as it generally is in the case of metallic conductors. Disturbances arise, owing to the heat evolved and absorbed in the secondary actions that take place at the electrode; and superadded to this we have in all probability an absorption or evolution of heat corresponding to the Peltier effect between different metals, of which we shall have to speak directly. Joule eliminated these disturbing influences by using a solution of copper sulphate with copper electrodes. In this case copper is dissolved from one electrode and deposited on the other, so that if we except the slight difference in the states of aggregation of the dissolved and deposited copper, the secondary processes are exactly equivalent, and must compensate each other. Joule[7] found that in a certain solution of $CuSO_4$ 5·50 units of heat were generated in a certain time, while in a wire of equal resistance 5·88 units were generated by an equal current in the same time. In a similar manner É. Becquerel[8] found that a current, which would produce a cubic centimetre per minute of explosive gas, generated in certain solutions of $CuSO_4$ and $ZnSO_4$ 0·213 and 0·365 units of heat; while the same current would have generated in wires of equal resistance 0·26 and 0·32 units respectively.

Peltier effect.

Reversible Heating Effects.—Peltier[9] was the first to discover an effect of this nature. He found that, when an electric current passes over a junction of antimony with bismuth, the order of the metals being that in which we have named them, there is an *evolution* of heat at the junction; and, when the current passes in the opposite direction, there is an *absorption* of heat, so that the temperature of the junction falls. Here, therefore, there is an effect which cannot vary as the square of the current strength, but must be some function of the current strength, whose *principal* term at least is some odd power.

The Peltier effect, as it is now called after its discoverer, may be demonstrated by inserting a soldered junction of antimony and bismuth into a Riess's thermo-electrometer. When the current goes $\overrightarrow{\mathrm{BiSb}}$, the fluid will rise in the stem, indicating absorption of heat; when it goes $\overrightarrow{\mathrm{SbBi}}$, the fluid will fall, indicating evolution of heat. Or we may use Peltier's cross, which consists of two pieces, one of bismuth BB′, and the other of antimony AA′, soldered together in the form of a cross (fig. 28). A and B are connected by a wire through a galvanometer G. A′ and B′ are connected with a battery C through a commutator D, by means of which the current can be sent either from A′ to B′ or from B′ to A′ through the junction. The thermo-electric current indicated by the galvanometer shows that the junction is heated in the first instance and cooled in the second.

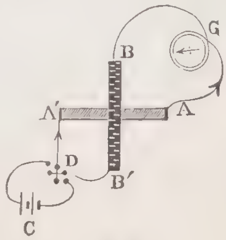

Fig. 28.

By leading the current of a Grove's cell for five minutes through a $\overrightarrow{\mathrm{BiSb}}$ junction, Lenz[1] succeeded in freezing a small quantity of water which had been placed in a hole in the junction, and previously reduced to 0° C. The temperature of the ice formed fell to $-4{\cdot}5°$ C.

Laws of Peltier effect.

The Peltier effect is different for different pairs of metals. Peltier and Becquerel[2] found that the metals could be arranged in the following order:—

$$\longrightarrow$$

Bi, Gs,[3] Pt, Pb, Sn, Cu, Au, Zn, Fe, Sb.

If the current pass across a junction of any two of these metals, cold or heat is generated according as the current passes the metals in the direction of the arrow or in the opposite direction; and the Peltier effect between the metals is greater the farther apart they are in the series. We shall see later on that this is none other than the thermo-electric series.

Von Quintus Icilius[4] showed that *the Peltier effect is directly proportional to the strength of the current.* He passed a voltaic current through a tangent galvanometer (serving to measure it) and a thermopile of 32 BiSb couples. The current was allowed to pass for a fixed time, then the battery was removed and the thermo-electric current of the pile measured by means of a delicate mirror galvanometer. The current of the battery heats the pile in part *uniformly* according to Joule's law: this causes no unequal heating of the junction, and therefore no thermo-electric current; and in part unequally, so that one set of junctions are cooler and the other warmer than the mass of the metal: this causes a thermo-electric current, which, since the temperature differences are small (see below, p. 90), may be taken to be proportional to the temperature difference, that is, to the double of the Peltier effect at each set of junctions.

It is interesting to note the analogy here with the polarization of an electrolytic cell. We turn a battery on to the thermopile, and polarize it, as it were. Then, when we remove the battery and close the pile, we get a return current, which might be called the polarization current of the thermopile.

In general the Peltier effect is, as we have seen, mixed up with Joule's effect, and makes itself felt by producing a disturbance at the junction. Thus Children[5] found that, when a strong current passed through two mercury cups joined by a thin platinum wire, so that the wire became red hot, the temperature of the mercury in the cups next the + pole of the battery rose to 121° F., while in the cup next the − pole the temperature was only 112° F. Frankenheim[6] studied the two effects together. He made a Peltier's cross of the pair of metals to be examined, passed a current I through the cross first in one direction and then in the other, and determined by means of a delicate galvanometer the thermo-electric current generated in each case, which is very nearly proportional to the heat produced. If a and b be the heat from Joule and Peltier effects respectively, and i and i' the observed thermo-electric currents, then $i = \mathrm{C}(a+b)$, $i' = \mathrm{C}(a-b)$; whence $a = (i+i') \div 2\mathrm{C}$, and $b = (i-i') \div 2\mathrm{C}$. In this way he found that a was proportional to I^2, and b to I. Thus the whole heat developed may be expressed by $a\mathrm{I}^2 \pm b\mathrm{I}$. We get in this way a verification of the results both of Joule and of Von Quintus Icilius.

Thomson effect.

Further experiments have been made on this subject by Edlund and Le Roux; and Sir W. Thomson was led by a remarkable train of reasoning to discover another reversible heating effect. We prefer to leave these matters for the present, to return to them when we consider thermo-electric sources of electromotive force.

The Peltier effect between metals and liquids and other reversible effects will also come up again under the Origin of Electro-motive Force.

Theory of heating effects.

Theoretical Deduction of the Formulæ.—The above formulæ for the heat developed in wires by statical and dynamical electricity may be deduced from a common formula, which can be deduced from Ohm's law.

Let P, Q be two points of a linear circuit, and let E be the difference between the potentials at P and Q, then, if there be no other electro-motive force in the portion PQ, the work done by a unit of + electricity in passing from P to Q is E. Hence, if I be the strength of the current, so that Idt units of electricity pass from P to Q in time dt, then the amount dw of work done by the current in time dt is E Idt. But, by Ohm's law, E = RI, hence

$$dw = \mathrm{RI}d^2t. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

Since the whole of this work is spent in heat, we may for w write H, which denotes the heat[7] generated in PQ. If the current be constant, we get immediately $\mathrm{H} = \mathrm{RI}^2t$, which is Joule's law (6). If the current be variable, $\mathrm{H} = \int \mathrm{RI}^2dt$, from which we may very easily deduce the formula for the discharge of a battery of Leyden jars. For, applying Ohm's law to the whole circuit whose resistance is R + S, we have, if U denote the potential of the inside coatings at time t, $\mathrm{I} = \frac{\mathrm{U}}{\mathrm{R}+\mathrm{S}}$. Also the capacity of each of the n jars being C, we have for the charge $q' = n\mathrm{CU}$, and $\mathrm{I} = -\frac{dq'}{dt} = n\mathrm{C}\frac{d\mathrm{U}}{dt}$. Hence

$$\mathrm{H} = \mathrm{R}\int \mathrm{I}^2dt = -\frac{n\mathrm{CR}}{\mathrm{R}+\mathrm{S}}\int \mathrm{U}\frac{d\mathrm{U}}{dt}dt = \frac{n\mathrm{CR}}{\mathrm{R}+\mathrm{S}}\;\frac{\mathrm{V}^2}{2}$$

$$= \frac{\mathrm{R}}{\mathrm{R}+\mathrm{S}} \cdot \frac{q^2}{2n\mathrm{C}}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

where q and V have the same meanings as in (3). (8) agrees with (3), except that we have reckoned the heat developed in a portion of the circuit whose resistance is R instead of S, as in (3). It appears, therefore, that the theoretical formula (7), when properly interpreted, covers both cases.

If there were a junction of heterogeneous metals in the part PQ of the circuit, at which the potential suddenly fell by an amount Π, then work equal to ΠIdt would be done by the current in passing over the junction, and we should have to write

$$d\mathrm{W} = \mathrm{RI}^2dt + \Pi \mathrm{I}dt. \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Had there been a *rise* of potential at the junction, we should have written − Π instead of + Π. If all the work done at the junction is transformed into heat, W = H as before, and for a constant current,

$$\mathrm{H} = \mathrm{RI}^2t + \Pi \mathrm{I}t. \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

The first term is Joule's, the second Peltier's effect. Here the coefficient of the Peltier effect appears as an electro-motive force. We shall return to this again.

Glowing, melting, etc., of wires.

Glowing, Melting, Volatilization, etc.—If a wire lost none of the heat generated in it, then for the same current, the rise in its temperature during a given time would vary as its specific resistance directly, and as the product of its specific heat and density into the fourth power of its diameter inversely. Thus, T, r, c, ρ, d denoting these quantities in the order named above, $\mathrm{T} \propto \frac{r}{c\rho d^4}$.

If we have a given battery of electro-motive force E, and a circuit connected with it of resistance R, and we insert a wire of length l specified in other respects as above, the current will be $\frac{\mathrm{E}}{\mathrm{R}+\mathrm{S}}$, where $\mathrm{S} = \frac{4lr}{\pi d^2}$. If the diameter of the wire be given, then $\mathrm{S} \propto l$; and $\mathrm{T} \propto \frac{\mathrm{S}}{(\mathrm{R}+\mathrm{S})^2}$, which is a maximum when R = S, that is, when the length of the wire is such that its resistance is equal to that of the rest of the circuit.

[7] Measured, of course, in dynamical equivalents.

Owing to our ignorance of the exact law of cooling, and of the manner in which the resistance and specific heat of most metals change at very high temperatures, it is very difficult to predict beforehand to what temperature a given current will raise a given wire. It is, as may be supposed, still more difficult to predict the effect of a given discharge from a Leyden battery. According to Riess, the phenomenon of glow in this case is complicated by concomitant effects of specific nature.[1]

If we assume Newton's law of cooling, *i. e.*, that the heat given out is proportional to the surface of the wire and to the elevation T of its temperature over that of the surrounding medium, then, I denoting the strength of the constant current which heats the wire, we have, when a constant temperature has been attained, $I^2 = \text{const.} \times Td^3$, for wires of same length and material but different diameters. If we compare the apparent brightness of the wires, by causing them to illuminate a screen at a constant distance off, and assume that the light given out is proportional to Td, then, if two wires of diameters d_1 and d_2 have the same apparent brightness, $T_1d_1 = T_2d_2$, and $I_1^2 \div d_1^2 = I_2^2 \div d_2^2$. In other words, the strength of current requisite to bring a wire of given length and material to a given brightness of glow varies directly as its diameter. A law of this nature is, of course, merely a rough approximation; Müller and Zöllner, however, have made experiments which agree with it within certain limits. The method of Zöllner is interesting (see Wiedemann's *Galvanismus*).

The temperature of a glowing wire is very sensitive to external circumstances, such as air currents, etc. These effects may be very strikingly shown by balancing the wire in a Wheatstone's bridge against a resistance of thick wire, a strong current being sent through the bridge.

The behavior of the wire in different gases is very remarkable. If a wire which is glowing in air be suddenly immersed in a jar of hydrogen or coal gas, the brightness will be very much reduced, in fact, in most cases the glow will entirely disappear.[2] This is owing to the greater cooling power of hydrogen, of which evidence is furnished by the experiments of Dulong and Petit.[3] The cooling power of different gases was shown by Grove. He arranged a platinum wire in a glass tube, which could be filled with different gases. The current of the same battery was sent through the wire and through a voltameter. When the tube was filled with hydrogen or olefiant gas, the amount of gas evolved in the voltameter per minute was 7·7 and 7·0 cubic inches respectively. The numbers for the other gases experimented on varied from 6·6 to 6·1. They stood in the following order:—CO, CO_2, O, air (2 atmos.), N, air (1 atmos.), air (rarefied), Cl. Experiments of a similar nature were made on liquids. Clausius carried out a calculation of the cooling effect of different gases, and found that the experimental results could be satisfactorily accounted for.[4]

When the strength of the current is sufficiently increased, the wire ultimately fuses, or even volatilizes. The phenomenon is in general complicated. In air, for instance, the wire burns, and the oxidization once started may take a greater share in raising the temperature than the current does, so that the destruction of the wire may take place under certain circumstances with a current, which, under other conditions, would scarcely make it glow. When discharges from a Leyden battery are used it is very difficult, if not altogether impossible, to get melting unaccompanied with mechanical disaggregation of the wire. The reader who wishes for further information concerning these matters, will find the sources sufficiently indicated in Wiedemann, Riess, and Mascart.

Popular experiments. This department of electricity is very fruitful in popular lecture-room experiments. We shall quote one or two of these, and refer the reader to popular treatises for more of the same kind.

On a sheet of thin card-board is pricked a design, generally what is understood to be a portrait of Franklin, two pieces of tinfoil are pasted on the ends of the card by way of electrodes, and between these a piece of gold leaf is laid. On the other side of the card is placed a piece of white paper or silk. The whole is then tightly screwed up between two boards. When an electric discharge is sent through the gold leaf it volatilizes, sending the disintegrated particles through the holes in the card-board. In this way an impression of the portrait is obtained.

If a current be caused to heat a pretty long thin platinum wire to dull redness, and a portion of the wire be cooled by applying a piece of ice to it, the remainder of the wire will glow much more brightly than before; whereas, if a portion be heated by a spirit-lamp, the reverse effect takes place. The reason is that the current is strengthened in the one case by the decrease of the resistance in the *cooled* part, and weakened in the other by the increase of resistance where the wire is heated.

When two curved metal surfaces rest upon each other, a current passing from the one to the other encounters considerable resistance at the small area of contact. The heat developed in consequence of this causes the parts in the neighborhood to expand very quickly when the contact is made. This very often gives rise to rapid vibratory movements in the conductors. The Trevelyan rocker[5] can be worked in this way (see art. HEAT), bells rung, etc. The best known experiment of the kind is Gore's railway. This consists of two concentric copper hoops, whose edges are worked very truly into the same plane. A light copper ball is placed on the rails thus formed, a current from two or three Groves is sent from one hoop to the other, and the ball set in motion. If the ball be very true, and the railway be well levelled, the energy supplied by the swelling at the continually changing point of contact is sufficient to keep up the motion, and the ball runs round and round, emitting a crackling sound as it goes.[6]

Electric light. *The Voltaic Arc.*—When two electrodes of volatile or readily disintegrable material forming the poles of a powerful battery (say 30 or 40 Grove's cells) are brought into contact and then separated, the current continues to pass across the interval, provided it is not too great. The conducting medium appears to be a continuous supply of heated matter, suspended in glowing gass or vapor. This phenomenon seems to be more akin to the subject we are now discussing than to the disruptive discharge of which we shall speak by and by. The light thus generated with a large battery, especially when electrodes of graphitic carbon are used, is brilliant in the extreme. It was thus that Davy first obtained the phenomenon.[7] With a battery of 2000 cells he obtained a luminous arc 4 inches in length, and when the carbons were placed in an exhausted receiver the arc could be lengthened to 7 inches.

The fact that the electrodes must be brought in contact in order to start the light is quite in accordance with what we know of the extremely small striking distance of even very powerful batteries. When the contact is made, the place where the electrodes touch, owing to its small section, is intensely heated; the matter begins to volatilize, and then the current is kept up by the quickly increasing cloud of metallic vapor and disintegrated matter. With a battery of 60 Grove's cells the arc once started has a certain persistence, for we may break the current for $\frac{1}{20}$th of a second or so, and the light will start again when the current is turned on afresh. We may start the light without bringing the electrodes into contact by causing a spark from a Leyden jar or an inductorium to pass across the interval.

Examination of phenomena. If an image of the voltaic arc be thrown on a screen by means of a lens, its constitution can be examined very readily. Four distinct parts at once strike us;—first, the dazzling white positive carbon, which assumes a crater-like shape after the current has passed for some time; second, the more pointed and if anything less brilliantly-white negative carbon, which is in general strewed with little beads of melted or at least softened carbon; third, the central core or streak of glowing matter, which has a white appearance, though it is considerably less brilliant than the carbon; fourth, the globe-shaped aureole which surrounds the whole, whose brilliancy is greatly inferior to that of the other parts, and whose color depends on the surrounding gas. If the electrodes be horizontal, the arc is in general curved upward by ascending air currents. Its form is also affected in general by the earth's magnetic action.

The hollowing out of the positive electrode is obviously due to a transfer of matter in the direction of the current. It is very easy to prove by a variety of conclusive experiments that there is such a transfer, mainly in the direction of the current, but also in part in the opposite direction. If we take a platinum point for positive, and a platinum plate for negative electrode, the matter carried to the plate forms a series of rings on it like the color rings of Nobili.

[6] This motion has been attributed to electro-magnetic action. Such an explanation is quite inadmissible.

[7] *Phil. Trans.*, 1821. According to Quetelet, Curtet observed the light between carbon points in 1802. Wied. *Galv.*, Bd. i. § 783.

If, on the other hand, the platinum plate forms the positive electrode, a series of slight excavations are formed where the matter has been torn away. There can be no doubt that the disintegration of the electrodes plays a very important part in the formation of the arc, for if we saturate the carbons with volatile matters, the brilliancy of the arc, the ease with which it forms, and its maximum length for given battery power are greatly increased. It is probably owing, in part at least, to the tearing away of matter at the positive electrode that the temperature there is in general highest. This effect is very marked in some cases. If we take a platinum point and a plate of the same metal for electrodes, the point glows through a considerable length when it is positive, but only at the end when it is negative. Again, when the light is generated between two platinum wires held crosswise at a small distance apart, the glowing portion is much longer on the positive electrode than on the negative.

Lighting, chemical, and heating powers.

The electric light is the only artificial light whose brilliancy can compare with the sun. Measured by its actinic properties simply, it is not so very far behind the great luminary; its spectrum is longer towards the violet, and it has accordingly great advantages when it is required to produce fluorescence (see art. LIGHT). Its great chemical power is also shown by the readiness with which it induces the combination of hydrogen and chlorine; by means of it underground buildings, such as the Catacombs, have been successfully photographed. Its illuminating powers have for a considerable time been employed in lighthouses, the current for its maintenance being furnished by powerful electro-magnetic machinery, and it is now proposed to employ the Gramme machine and the electric lamp to light streets and public buildings, manufactories, etc. It was used for war purposes during the last siege of Paris, and in the Russo-Turkish war on the Danube; and further applications to torpedo warfare have been contemplated.

In most of these applications of the electric light it is important that the arc should be of constant length, and maintain a fixed position. Owing to the unequal consumption of the carbons, special appliances are required to secure the fulfilment of these conditions. The best known and perhaps the most efficient of the older electric lamps is that devised by Foucault. It consists of a piece of clockwork, which moves the carbons towards each other with relative speed nearly equal to that at which they are consumed. The machinery is controlled by a detent worked by an electro-magnet, which is excited by the current which feeds the arc. When the carbons are too far apart the electro-magnet is weakened and releases the detent. The machinery then moves the carbons until the current is strong enough to enable the electro-magnet to apply the detent again. This apparatus works well enough for lecture-room and other purposes, but has not given perfect satisfaction in industrial applications. Accordingly many devices have been proposed, more especially of late years, to supersede it. One of the simplest and it would appear most effective of these is the electric candle of Jablochkoff. This consists simply of two carbons, separated from each other by a plate of kaolin. The arc passes between the carbons, and plays over the kaolin, which gradually melts away like the wick of a candle, and by its incandescence greatly helps the brightness of the light.[1]

The heating powers of the electric arc are no less remarkable; platinum and iridium melt in it like lead, and volatilize. In this way the spectra of the glowing vapor of these metals can be projected on a screen. Almost nothing seems to resist the elevated temperature of the arc. Despretz generated it in vacuo by means of 500 to 600 cells of Bunsen, and observed pieces of carbon volatilize like a piece of heated iodine, while the carbon vapor condensed on the walls of the receiver in the form of a crystalline powder. Flint melted to a glassy mass, and boron behaved similarly, while cylinders of retort carbon softened and bent into an S-form.

The voltaic arc behaves in many respects like an ordinary electric current. It is affected by the magnet, for instance, as an ordinary current would be. Owing, however, to the variety of transformations of energy taking place, it is difficult to estimate accurately the resistance and electro-motive force of the arc. Edlund made experiments which seemed to show that a certain minimum electro-motive force in every case was necessary for the maintenance of a continuous arc, yet the arc does not appear to consist of a series of disruptive discharges, for its image in a rotating mirror is a uniform band. It would seem, therefore, as if polarization in some form or other were present. Edlund, in fact, found that when a galvanometer was substituted for the battery by which the arc was formed a considerable current was obtained, which might have an origin similar to that of electrolytic polarization, or be a thermo-electric effect.[2] For further details on these and other matters connected with the electric light, we refer the reader to the admirable account of Wiedemann (*Galvanismus*, Bd. i. § 701 *sqq.*), from which most of the above is taken.

Disruptive Discharge, Light Effects, etc.

Phenomena of disruptive discharge.

A definite meaning has already been attached to the term disruptive discharge; the object of the present section is to consider this phenomenon a little more closely in several particular cases. The disruptive discharge proper is in general accompanied by sound, heat, light and mechanical effects, very often by all four. The attendant luminous phenomena have absorbed by far the greatest share of the attention of experimenters, partly, no doubt, on account of their great variety and wonderful beauty. It would be a hopeless task to endeavor, within the limits set us here, to give even a meagre summary, not to speak of a critical account, of all the experiments and observations that have been made on this subject. The scientific investigator will find sufficient guide for his reading in the three standard treatises of Riess, Wiedemann, and Mascart. Riess is particularly interesting in his account of the older experiments; Wiedemann, on the other hand, gives elaborate accounts of the more modern results of De la Rive, Plücker, Hittorf, and others.

Theoretical considerations.

When induction is exerted across a di-electric, we may consider the action at any point of it in one or other of two ways. We may regard the resultant electro-motive force arising from the action at a distance of all the free electricity in the field as tending to separate the two electricities in the molecules of the di-electric. In this view, we might measure the di-electric strength of the medium by the value of the electro-motive force, when the electricity is on the point of passing from one molecule to the next. We might, on the other hand, consider, with Faraday and Maxwell, that the di-electric is the seat of a peculiar kind of stress, consisting of a tension p along the lines of force, and an equal pressure perpendicular to them, p being equal to $\frac{K}{8\pi}R^2$ (Maxwell, vol. i. § 104). We shall adopt the latter alternative, and when we speak of tension henceforward it means $\frac{K}{8\pi}R^2$. In this view the di-electric strength may be defined as that tension under which the di-electric just begins to give way. The reader who prefers the other way of looking at the matter will find no difficulty in translating any statement from the one language into the other.

We have started by considering any point of the di-electric, and it is obvious that the di-electric (supposed homogeneous) will first give way at that point which first reaches the limiting tension ϖ; just as an elastic solid begins to give way where the stress first reaches the breaking limit. It may be proved, however, that R^2 cannot have a maximum value at any point where there is no free electricity, which shows us at once that the point at which the limiting tension is first reached must always be on *some* electrified surface, in general therefore on the surface of one of the conductors of the system.[3] Disruptive discharge, thus begun at the surface of a conductor, spreads out into the di-electric. Its farther course is influenced by a variety of circumstances very hard to define in the great majority of cases.

An attempt will be made by and by to give an idea of the varieties of luminous discharge that arise in this way; meantime we concentrate our attention on a feature common to all disruptive discharges, viz., the definite limiting tension at which under given circumstances they begin.

Di-electric strength.

Di-electric Strength of Gases.—The earlier measurements bearing on this subject were conducted under circumstances which render a comparison

---

[1] See *Nature*, Sept., 1877.

[2] Wiedemann explains Edlund's results by means of an "Uebergangswiderstand." It is difficult to understand how in this way a return current could arise.

[3] The di-electric is supposed to be homogeneous. Prof. Maxwell has pointed out that exceptions might occur in the case of a weak di-electric interposed between two strong ones, *e.g.*, a current of hot air passing through cold.

Striking distance.

of the results with the theory, as at present developed, very difficult. Harris found that the striking distance between two balls connected with the armatures of a condenser was directly proportional to the charge of the condenser as measured by a Lane's jar. Riess used a Leyden battery, and varied the number of jars and the charge of the battery. The balls of his spark micrometer were of diameters 5·7 and 4·4 lines respectively, while the distance between them varied from 0·5 to 2·5 lines. Under these circumstances, he found the striking distance to be proportional to the charge of the battery directly, and to the number of jars inversely. The results of Harris and Riess might be summed up in the statement that the striking distance between two balls connected with the armatures of a condenser varies as the electro-motive force or difference of potential between the armatures. This result is purely empirical, and must not be extended beyond the experimental limits within which it was found. Even Riess's experiments themselves show that the striking distance increases more rapidly than the difference of the potentials.

The experiments of Knochenhauer[1] led to a similar result. Gaugain[2] made experiments of the same kind through a wider range of striking distances, and found, in conformity with the result of Riess, that, with balls of 10 or 15 mm. diameter, the striking distance is proportional to the potential difference between the balls, when the distance between them lies between 2 and 5 millimetres. Beyond these limits the ratio of potential difference to striking distance falls off; whereas, for smaller distances, it increases very rapidly. He also found that the deviation from the law of Harris and Riess is more marked when unequal spheres (3 mm. and 10 mm.) are used, and still more when a ball (3 mm. diam. used as + electrode) and a disc (35 mm. diam.) were used as electrodes. Experiments leading to similar conclusions are cited by Mascart,[3] who finds that, for spheres of diameter 3 to 5 centimetres, the striking distance for given potential difference is sensibly the same; whereas for plates, both the striking distance and the law of the whole phenomenon is different. The same experimenter examined the striking distances between two equal balls (3 cm. diam.) from 1 mm. up to 150 mm. Taking the potential difference for one millimetre as unity, he found for 10, 20, 40, 80, 150 mm. the potential differences 8·3, 11·8, 15·9, 20·5, 23·3. The deviation from proportionality is obvious; the potential differences in fact tend to become constant. Wiedemann and Rühlmann, in their experiments on the passage of electricity through gases (see below, p. 58), made some experiments on the influence of the form and distance of the electrodes. They used two brass balls of 13·8 and 2·65 mm. diameter respectively, and sent between them the discharges of a Holtz machine. The distance (δ) between the nearest points varied from 3 to 22·3 mm. They found that the quantity of electricity (y) required to produce discharge, could be represented by the formulæ $y = \mathrm{A} - \frac{\mathrm{B}}{\delta}$ and $y = \mathrm{C} + \mathrm{D}\delta^2$, according as the larger sphere formed the positive or negative electrode. The constants A, B, C, D depend on the pressure, which varied in these experiments between 25 and 60 mm. of mercury.

Sir W. Thomson's experiments.

In most of the experiments that have just been described the effect of the form of the electrodes and the surrounding conductors could not be estimated theoretically. Experiments in which the theoretical conditions are simple have been made by Sir Wm. Thomson.[4] The spark was taken between two parallel plates of considerable area; one of these was plane, and the other very slightly curved, to cause the spark to pass always at a definite place. The electrical distribution on the opposing surfaces can be found (see above, Math. Theory of Electrical Equilibrium), as if the plates were plane and of infinite extent. This distance between the plates was measured by a micrometer, the contact reading being determined by observing when the electricity ceased to pass between the plates in the form of a spark. The potentials were measured in absolute electro-static (C.G.S.) units, by means of Thomson's absolute electrometer (see art. ELECTROMETER). The limiting tension or di-electric strength is given in each case in grammes per centimetre, the formula for calculating it being

$$p = \frac{V^2}{8\pi \times 981{\cdot}4d^2},$$

in which V represents the potential difference or electromotive force between the plates, and d the distance in centimetres. If we take the older view of Poisson's time, that the action of the electricity on the surface of a conductor is simply a fluid pressure, then p represents that pressure.

If we could consider the air between the plates as a homogeneous di-electric, then, for air at a given pressure (and temperature?) and given state of dryness, p, which measures its di-electric strength, would have a constant value independent of the distance between the plates, and V would be proportional to d. A glance at Sir Wm. Thomson's[5] tables shows that this is not the case. For a distance of ·00254 cm., $p = 11{\cdot}290$, whereas for a distance ·1524, $p = {\cdot}535$. It appears, therefore, that the di-electric strength of a thin stratum of air is much greater than that of a thick one. It is very difficult to understand why this should be so. "Is it possible that the air very near to the surface of dense bodies is condensed, so as to become a better insulator; or does the potential of an electrified conductor differ from that of the air in contact with it, by a quantity having a maximum value just before discharge, so that the observed difference of potential of the conductors is in every case greater than the difference of potentials on the two sides of the stratum of air by a constant quantity equivalent to the addition of about ·005 of an inch to the thickness of the stratum?"[6] It is remarkable that the limiting tension should be so small, somewhere about half a gramme per sq. cm., as compared with the atmospheric pressure, which is about 1032 gm. per sq. cm.

A series of absolute measurements of the potential required to produce a spark between equal spheres at different distances has been made by Mascart. The method employed was very ingenious.[7]

Effect of pressure, etc.

Harris.

Effect of Pressure, Temperature, etc., on the Di-electric Strength of Gases.—The di-electric strength of a given gas depends on its pressure, or at all events on its density. Harris, who experimented on this subject, inclosed two balls in a receiver which could be exhausted to any required degree, and connected them with the armatures of a battery of jars. He found that the charge which had to be given to the battery in order to produce a spark between the balls was proportional to the density of the air in the receiver, while it seemed to be independent of its temperature. This amounts to asserting that the difference of potentials required to produce a spark between the balls is proportional to the density of the gas and independent of its temperature. Since we keep the distance between the balls the same throughout, this statement is equivalent to saying that the di-electric strength of a gas varies directly as its density, and does not depend on the temperature. Masson, using the method which Faraday had employed in comparing the di-electric strength of gases (*vide infra*) arrived at the same conclusion as Harris. Knochenhauer, however, experimenting with pressures ranging from 3 to 27·4 inches of mercury, found that for a given interval the difference of potentials required to produce disruptive discharge was proportional to the pressure increased by a small constant quantity.

Faraday.

Faraday, in the 12th and 13th series of his *Experimental Researches*, examines this subject; and the reader who desires to have a clear idea of what the issues involved really are will do well to begin by carefully studying Faraday's results, and still more his views on this matter. Faraday directs his attention to the specific behavior of different gases.

The gas to be examined was introduced into a receiver in which were arranged two balls s and l, of diameters 0·93 in. and 2·02 in. respectively, at a constant distance 0·62 in. apart. Two balls, S and L, of diameters 0·96 in. and 1.95 in., were placed on suitable insulating supports outside the receiver. S and s were connected with an electric machine, and l and L to earth. The distance u between S and L could be varied at will; if it was greater than a certain value β, the sparks always passed between s and l in the receiver; if it was less than a certain value a, they always passed between S and L in the outer air. It might have been expected that a and β would be equal, or at least very nearly so, *i.e.* that there would be one definite value of u, for which the spark would hesitate between the alternative intervals. This is not so, however. Nor again is the value of u the same when s and l are negative as when they are positive. The following table will illustrate these points, as well as the relations of the different gases:—

---

[7] *Electricité*, t. i. § 481.

Gas.	*s* and *l* positive.			*s* and *l* negative.		
	α	β	Mean.	α	β	Mean.
Air	0·60	0·79	0·69	0·59	0·68	0·63
Oxygen	0·41	0·60	0·50	0·50	0·52	0·51
Nitrogen	0·55	0·68	0·61	0·59	0·70	0·64
Hydrogen	0·30	0·44	0·37	0·25	0·30	0·27
Carbonic acid	0·56	0·72	0·64	0·58	0·60	0·59
Olefiant gas	0·64	0·86	0·75	0·69	0·77	0·73
Coal gas	0·37	0·61	0·49	0·47	0·58	0·52
Hydrochloric acid	0·89	1·32	1·10	0·67	0·75	0·72

It will be seen that the different gases present considerable variety, and cannot be classified in any way so as to connect the di-electric strength with any other physical property. The numbers given cannot be regarded as *measuring* the di-electric strength, owing to the disturbing influences which cause the inequality of α and β. This inequality is not by any means small; *e.g.*, for air the uncertainty amounts to about 32 per cent. These experiments show very clearly that the sign of electrification of the surface at which the discharge begins has a great effect on the limiting tension. The discharge passes much more readily from a small ball to a large one when the former is negative than when it is positive. Faraday made a variety of experiments to elucidate this point, and he was driven to the conclusion "that, when two equal small conducting surfaces equally placed in air are electrified, the one positively the other negatively, that which is negative can discharge to the air at a tension a little lower than that required for the positive surface, and that, when discharge does take place, much more passes at each time from the positive than from the negative surface."

Positive and negative limiting tension.

The inequality of α and β may be due to various causes, among which may be mentioned the charging of the glass of the receiver, dust, etc., in the air, heating of the air, and the presence of finely divided metal dispersed by preceding sparks. The last of these causes would account to a considerable extent for the fact that the sparks show a tendency to persist in a path once opened, and that the interval $\beta - \alpha$ is less for the negative spark, which starts at a smaller limiting tension, and may therefore be supposed to produce less mechanical effect.

Wiedemann and Rühlmann.

Wiedemann and Rühlmann have recently taken up this subject in a research which has already been alluded to.[1]

The gas and the spark terminals were inclosed in a cylindrical metal receiver with rounded ends. A small window allowed the light from the spark to fall on a rotating mirror fixed on the axis of a Holtz machine, which furnished the electricity. The images of the successive sparks were observed by means of a heliometer. One-half of the divided object-glass was moved until one of the images of one discharge coincided with one of the images of the next; then a similar coincidence was brought about by displacing the half-lens in the opposite direction. The difference (y) of the two readings on the micrometer of the heliometer measures the rotation of the disc of the Holtz machine between the two sparks. Preliminary experiments showed that the amount of electricity furnished by the machine while the disc moves through a given angle is independent of the angular velocity of the disc. It varies from day to day, however, according to the quantity of moisture in the air and the arrangement of the machine; but, on the principle just laid down, correction can easily be made by taking the reading each day of a galvanometer through which the current of the machine is sent. It follows, therefore, that y is proportional to the quantity of electricity which passes at each discharge through the gas, and by means of a galvanometer observations on different days can be compared.

It was found that at the lowest pressures worked with (·5 to ·25 mm. of mercury) the discharge of the Holtz machine was still discontinuous; and that in all the experiments the tension at the electrodes was such that the discharge was independent of the nature of the metal,—in other words, that the disintegration of the electrode played no essential part in the discharge.

The quantity of electricity required to effect a discharge, other things being equal, increases with increasing pressure. This increase is at first rapid, then slower, and at high pressures it is nearly proportional to the increase of pressure. It was found that y could be expressed with sufficient accuracy in terms of the pressure p by the empirical formula, $y = A + Bp - Cp^2$, in which the constants A, B, C, depend on the size and insulation of the electrodes, their distance apart, and so on.

They arrange the gases in the following order of dielectric strength:—hydrogen, oxygen, carbonic acid, air, nitrogen. It is not a little remarkable that this is the order given by Faraday in the second column (the best) of the results we quoted above.

They find, in agreement with Faraday, that a greater quantity of electricity is required to bring two unequal spheres to the discharging point when the small one is positive than when it is negative. When two equal spheres are used, the value of y is least when both are insulated, greater when the positive sphere is uninsulated, and very much greater when the negative one is uninsulated.

All this is in accordance with theory, provided we assume with Faraday that the limiting tension is greater at positive than at negative surfaces. For example, suppose the surface densities corresponding to the limiting positive and negative tensions to be P and N ($P > N$), and consider the case of two equal spheres of radius a, at so great a distance c apart that $\left(\frac{a}{c}\right)^3$ may be neglected, then by taking three consecutive images the reader will easily find that the charges which must be given to either ball in the case where both spheres are insulated and equally charged, and to the negative ball in the case where the positive ball is uninsulated, and to the positive ball when the negative ball is uninsulated, must be $\left(1 - 3\frac{a^2}{c^2}\right)4\pi a^2 N$, $4\pi a^2 N$, $4\pi a^2 P$, respectively, in order to produce discharge. The discharge begins at the negative ball in the first two cases, and at the positive ball in the third, and the quantities are obviously in ascending order of magnitude when P is $>$N.

High pressures.

The di-electric strength goes on increasing when the pressure is raised above the atmospheric pressure. Cailletet[2] found that a powerful induction coil worked by eight large Bunsen cells was powerless to effect discharges across ½ mm. of dry gas at a pressure of 40 or 50 atmospheres.

Minimum strength.

On the other hand, however, the di-electric strength does not diminish indefinitely as the pressure decreases, but reaches a minimum.

Morren and De la Rive[3] have sought to determine this minimum di-electric strength by measuring by means of a galvanometer the mean intensity of the current sent through the gas by an inductorium so arranged that only the direct induction current passes; they thus obtain what they call a minimum *resistance*. Morren gives the pressures corresponding to this minimum for various gases; they lie between 0·1 and 3·0 mm. It may be questioned whether any very definite meaning can be attached to results of this kind; for the discharge is discontinuous, and *resistance* in the proper sense of the term cannot be spoken of.

Strength of vacuum.

It is clear, however, that a minimum di-electric strength must exist; for, if we go on improving our vacuum, we find that our ordinary machinery fails to send electricity through any considerable length of the exhausted space.

Morgan[4] seems to have been the first to discover that the electric spark would not pass in a vacuum. Having carefully boiled the mercury in a barometer tube, so as to remove the last traces of moisture, he found that the inductive discharge caused by electrifying a piece of tinfoil on the outside of the tube would no longer pass to the mercury, and cause the luminous phenomena usually seen under such circumstances. Masson repeated this experiment in a more satisfactory form. Gassiot[5] greatly improved the exhaustion of vacuum tubes by filling them with CO_2, pumping out as usual, and then absorbing the residual gas by fusing a piece of KHO previously inserted into the tube. He constructed tubes in this way which had sufficient di-electric strength to insulate the pole of his great battery of more than 3500 Zn. Aq. Cu. cells. Hittorf and Geissler[6] have constructed vacuum tubes (by pumping with a Geissler's pump, and heating the whole to 400° to 500° C.) in which the opposition to the discharge of an interval of ½ mm. between two platinum electrodes was greater than that offered by 15 or 20 centimetres of ordinary air.

Progress of disruptive discharge.

Different Forms of the Discharge in Gases.—We have said that the subsequent progress of the disruptive discharge when once begun is influenced by a great variety of circumstances.

[4] *Phil. Trans.*, 1785.

[5] *Phil. Trans.*, 1859.

[6] *Pogg. Ann.*, 1869.

The beginning of the discharge evolves heat, which rarefies the neighboring air, and therefore weakens its di-electric strength. Owing to this cause the discharge once started tends to go on. Again, if any considerable quantity of electricity escapes into the ruptured di-electric at the first burst, this relieves the tension at the surface of the conductor. On the other hand, the progress of part of the electricity towards the opposing conductor raises the tension at the surface of the latter, so that disruptive discharge is provoked or helped there. If the initial tension is considerable, or the quantity of electricity which passes to begin with very great, glowing metal particles are shot forth into the di-electric, causing a reduction of its strength, which will be very different in different directions. Motions of the air play a great if not a preponderating part in many forms of the discharge. The electrification, etc., of the walls of the tube, and the form of the electrodes and of the tube, both in the neighborhood of the electrodes and at a distance from them, are as important in their influence on the continuance of the discharge as they are on its start. And, last but not least, much depends on the way the electricity which produces the discharge is furnished,—on the nature of the electro-motor, in short. Although we have not yet exhausted the influencing conditions, we have probably said enough to convince the reader that little aid is to be hoped for in this matter from considerations *a priori.* There is a great deficiency even in proximate principles to guide us in the maze of experimental detail; and although most of the experiments are beautiful beyond all conception, yet the mere narration would scarcely interest the reader. Our description of the department will, therefore, consist simply in going round the boundary.

The luminous appearances may be roughly classed under the forms of spark, brush, glow and convective discharge, and dark discharge.

Spark.

At the ordinary atmospheric pressure, the disruptive discharge between two conductors at a moderate distance apart takes place in the form of a brilliant sharply bounded streak of light, whose apparent breadth is in general small. For small distances the spark is straight, and has the appearance of being thicker, or at least more brilliant, at the ends than in the middle. When the distance is considerably increased the spark assumes the characteristic zig-zag form seen in forked lightning. It seems occasionally to be absolutely broken by perfectly dark spaces. The duration of the discharge in this form, more especially when the resistance of the discharging circuit is very small, as tested by a rotating mirror, appears to be exceedingly short.

We have taken photographs of the sparks of a Holtz's machine by simply moving the camera containing the sensitized plate vertically upwards past the electrodes of the machine. The result is a column of perfect photographs, quite unblurred by the jarring, etc., of the camera stand. Again, if a disc painted with white and black sectors be caused to rotate very rapidly, it appears in ordinary light to have a uniform gray color; but when it is viewed by the light of an electric spark the sectors are seen exactly as if the disc were at rest, which proves that the illumination lasts for a very short time. Masson founded on this experiment a beautiful method for measuring the intensity of the light given out by the spark. A description of his apparatus, with an account of his results, will be found in Mascart.

The color of the spark in air is bluish,[1] but at the same time its great brilliancy gives an impression of whiteness. In nitrogen the appearance is much as in air, only the color tends more to bluish purple, and the spark is more sonorous. In oxygen the spark is whiter and less brilliant than in air; in hydrogen crimson-colored; in carbonic acid greenish; in hydrochloric acid white, and never broken by dark parts; in coal gas green or red, with occasional dark parts. If the spark be carefully examined, especially when the pressure is greater than an atmosphere, it will be seen that the central bright streak is surrounded by an envelope, of somewhat nebulous form, and of a lavender-blue color. This envelope tends to spread over the negative electrode, where it is more conspicuous as compared with the central streak than elsewhere. This envelope appears to be due to the glowing metal particles torn from the electrodes. It has, unlike the central streak, a sensible duration, on account of which it happens in many cases that a much greater quantity of electricity passes through it than through the infinitely more brilliant but less enduring part of the discharge. The envelope can be actually separated from the streak by a current of air properly directed, or by the action of a magnet (*vide infra*, p. 69.)

Brush.

When the discharge in air at the atmospheric pressure takes place between a *salient* but *not pointed* part of one conductor and another conductor *of considerable surface* (*e.g.*, between one sphere 2 cm. diameter and another 13 cm. diameter), the luminous appearance very often takes a characteristic form, which has been called the brush discharge. The name is to a considerable extent descriptive of the phenomenon; if the word broom had been applied it would have been even more appropriate, and a rough idea of the variety of forms the brush may assume will be obtained by thinking of the various forms of the domestic article in question. At the surface of the smaller conductor appears a short, straight, luminous stem differing in appearance very little except in brightness from a *spark.* From this radiate a series of twig-like branches of much inferior brilliancy, having a purplish-violet color. These subdivide in many cases into still smaller ramifications, and are ultimately lost in the medium. When the large conductor is either altogether absent or very distant, the general tendency of the branches is to spread outwards more and more in all directions; but when the large conductor is brought nearer, the branches have a tendency to bend down towards it, so that the whole assumes an ovoid shape. The brush is generally accompanied by a crackling or hissing sound, or even a musical note. On approaching the hand or a conductor of extended surface, the pitch of this sound rises considerably. This at once suggests that the brush is an intermittent phenomenon. That this really is so was clearly proved by Wheatstone in one of the earlier applications of his rotating mirror.[2] Wheatstone saw in his mirror not one image of the brush, but several arranged in succession at regular intervals. Each of these images corresponds to a single discharge, and each appears less complicated than the brush as viewed by the unaided eye, which is, in reality, a superposition of a considerable number of brushes, the number depending on the time taken by a light impression to fade on the retina. At the same time each individual image is a little drawn out in the direction of motion of the mirror, which shows that the brush has a sensible duration. Faraday speculates very acutely concerning the nature of the brush discharge (see *Exp. Res.*, 1425 *sqq.*). He finds that, although it is generally accompanied by a current of air, yet it is not always or necessarily so. He also carefully illustrates the difference between the positive and negative brush. If we have a small ball on the end of a wire projecting freely into the air, the positive brushes[3] obtained from it are much larger and finer than the negative brushes so obtained. Again, if we charge a large metal ball positively, and bring an uninsulated metal point up to it, a star appears on the point, which gets brighter and brighter as the point approaches the sphere, but the form does not change until the distance is very small. If the sphere be charged negatively, the star appears as before when the distance is considerable, but at a moderate distance (1 to 2 inches) a brush forms, and when the distance is still farther reduced a spark passes. It seems, therefore, that the negative discharge keeps its form unchanged under considerable variety of influencing circumstances, whereas the form of the positive discharge is more readily affected. The explanation of these differences he finds in the fact, which he established by experiments already alluded to, that the limiting tension is smaller at positive than at negative surfaces; so that, *cœteris paribus*, the negative discharge occurs oftener than the positive discharge; but, on the other hand, when the latter does occur, more electricity passes. This, no doubt, accounts for the lower pitch of the sound of the negative brush, and the greater extent and brilliancy of the positive one. Faraday found great differences in the character of the brush in different gases; in none apparently does it reach the brilliancy attained in air or nitrogen. He also observed that rarefaction up to a certain point favored the production of brushes.

Glow.

When discharge takes place from the rounded end of a wire projecting freely into the air, the brush is very often replaced by a quiet phosphorescent glow, which covers a greater or less extent of the end of the wire.

---

[1] Faraday, *Exp. Res.*, 1422.

[2] *Phil. Trans.*, 1834, etc.

[3] By positive brush, of course, is meant brush emanating from a positively charged surface.

The noise which accompanies the brush is entirely absent in this form of the discharge, and the means by which the brush can be analyzed into a series of successive discharges give no corresponding result for the glow. In the rotating mirror it simply stretches out into a uniform band of light. The glow is therefore either a continuous discharge or an intermittent discharge of incomparably shorter period than the brush. Diminishing the discharging surfaces favors the production of glow.[1] Increase of power in the electric machine which is furnishing the electricity has a similar effect. Rarefaction of the air has also a great effect in facilitating the production of glow, especially in the case of negative glow, which is extremely hard to produce in air at common pressures. In Faraday's opinion, the star which is obtained with a positive sharp point is a positive glow; but he thinks it not improbable that the negative star is not a negative glow, but a small negative brush. The glow is invariably associated with a current of air to or from (generally both) the glowing conductor. Everything that favors this air-current increases the glow; *e.g.*, a brush may sometimes be converted into a glow by properly directing an air-current near it. Again, everything that prevents or retards the formation of an air-current has a similar effect on the glow: a glow can be converted into a brush in this way. Lastly, everything which tends to prevent abrupt variation of the tension favors the glow, and everything having an opposite tendency is destructive of it. Faraday concludes, therefore, that the glow is due to a gradual discharge by convection, in which the agents are the particles of the gas. The order of the appearance of spark, brush, and glow at positive and negative surfaces is, in general, the same; but the gradation is different. Positive spark does not pass into brush so soon as negative spark does; but, on the other hand, positive brush turns to glow long before negative brush.

Convective discharge.

Intimately connected with the glow is the convective discharge, if indeed they are not degrees of the same phenomenon. "The electric glow is produced by the constant passage of electricity through a small portion of air in which the tension is very high, so as to charge the surrounding particles of air which are continually swept off by the electric wind, which is an essential part of the phenomenon."[2] Now there seems little reason to doubt that at lower tensions[3] discharge of this kind may occur without the luminous phenomenon at the surface of the conductor. If this be so, then the convective discharge is only a different degree of the glow discharge.

Discharge by convection plays a very important part in all electro-statical experimenting. The air in the neighborhood of an electrified conductor gets charged, forming an electrical atmosphere, which surrounds the conductor, being more extensive in the neighborhood of salient angles than elsewhere. Such electrical atmospheres are often a source of great inconvenience in the laboratory and the lecture-room when delicate electrical experiments are in progress.

A curious little instrument, called the electrical tourniquet or windmill, depends for its action on the electrical wind which accompanies convective discharge. A small rectangular cross, with equal arms, is made of light wire; the extremities of the arms are bent through a right angle in the plane of the cross, so as to point all one way. The little cross thus made is poised, like a compass-needle, on a vertical wire connected with an electrified conductor. Convective discharge takes place at the points, giving rise to an electrical wind, the reaction of which causes the little machine to revolve with great rapidity. If the experiment be conducted in the dark, a glow usually appears on the revolving points. The experiment also succeeds when the cross is immersed in a non-conducting liquid.

Dark interval.

We have already alluded to the dark spaces that sometimes appear in the spark in gas at the atmospheric pressure. Faraday observed that a phenomenon of this kind was very common in coal gas. When the discharge takes place in highly rarefied gas, a dark space of this kind almost always separates the positive from the negative light, its situation having a certain degree of fixity with respect to the negative, but not to the positive electrode. It is very difficult to form an idea of the exact nature of the discharge which takes place in this space. Discharge there undoubtedly is of some kind; and pending further investigation, Faraday called it the dark discharge. The fact that its real nature is still undiscovered amply justifies the separate name. Faraday found that it occurred in discharges that pass almost instantaneously, and concluded that it could hardly be due to convection of the ordinary kind, which requires time. De la Rive and Hittorf have made out many peculiarities connected with its appearance in vacuum tubes, the phenomena in which we now attempt briefly to describe.

Phenomena in rarefied gases.

A variety of forms may be given to the vessel in which the rarefied gas to be experimented on is inclosed.

One of the most common used to be the electric egg, which is simply an oval glass vessel furnished with two small metal spheres for electrodes; the stems which carry these electrodes pass air-tight through tubes cemented to the ends of the vessel; the stem which supports the whole is perforated and fitted with a stop-cock, so that the apparatus can be exhausted to any required extent and then temporarily closed. The commonest of all instruments of this kind now-a-days is the Giessler tube. This is simply a glass tube, into which are fused two electrodes of platinum or other metal; a capillary tube allows the apparatus to be connected with an air-pump, and exhausted; when this is done, the capillary tube is sealed up by means of a spirit-lamp. A very common form of such tube is the spectrum tube (see art. LIGHT), consisting of two wider parts, connected by a capillary part, in which the light of the discharge is much more intense than elsewhere. Complicated tubes of all kinds have also been constructed as electric toys.

The reader must not forget that the form of the tube exercises a great influence on the phenomena, whether at the positive or negative electrode. In the summary description that follows, the electric egg is referred to, unless it is otherwise stated. We further assume that the electro-motor used gives currents in one direction only. A Holtz machine would satisfy this condition, within certain limits at least.

When the gas is rarefied to a considerable extent, the spark loses its sharp outline, becomes interspersed with nebulous portions, and by and by loses its characteristic form altogether. As the rarefaction goes on, the discharge ceases to reach from the positive to the negative electrode. The latter now displays a patch of lavender-blue light, separated from the positive light by a dark interval, the length of which depends on the distance between the electrodes. In certain cases the positive light terminates in a cup-shaped depression, whose concavity is turned towards the negative electrode. As the rarefaction is still further increased, the positive light tends more and more to fill the tube, although in general it recedes from the negative electrode, over which, on the other hand, the beautiful lavender glow spreads more and more, exhibiting at the same time a growing tendency to fill a limited space *surrounding* the electrode. At a still higher degree of rarefaction, the positive light, which now occupies a considerable space, and takes a shape more or less corresponding to that of the inclosing vessel, is divided transversely into a number of cup-shaped striæ, separated from each other by darker intervals. These striæ vary in form and appearance considerably, according to circumstances. In the neighborhood of the positive electrode, their concavity is turned towards the positive electrode; but towards the other end of the positive light, the concavity may be turned the other way, especially in the electric egg. The positive light, in vacuum tubes, shows therefore the same remarkable variability, and the negative light the same measure of stability that Faraday remarked in gas at ordinary pressures. The color of the positive light varies very much in different gases; in nitrogen and air its rosy-red color contrasts very sharply with the blue of the negative light. The negative light is remarkable for its power of producing fluorescence. It is very dependent as to its extent on the form and size of the uncovered surface of the electrode; anything placed on the electrode cuts it off sharply, as if the light were projected from the electrode and stopped by the obstacle. Disintegration of the negative electrode also goes on very rapidly, so that, after a vacuum tube has been used for some time the glass all round the negative electrode is blackened, browned, etc., as the case may be, with a deposit of finely divided metal. The quantity as well as the quality of this deposit depends very much on the nature of the metal; it is smallest with aluminium, which is on that account much used for electrode terminals. The negative light occasionally shows one, two, or even three stratifications; but in this respect it never equals the positive light. When the rarefaction is carried to the utmost, both positive and negative lights fall off greatly in splendor. The negative light contracts more and more in upon the electrode, and confines itself even there to a small patch near the end, showing, however, a tendency to pass along the axis of the tube towards the positive electrode. The positive light, on the other hand, gradually draws inwards, till at last it is only a star on the end of the electrode, which now disintegrates, owing to the great tension.

---

[1] *Exp. Res.*, 1527.

[2] Maxwell, *Electricity and Magnetism*, i. § 55.

[3] The reader will not forget the exact sense in which we use the word tension. Of course low tension does not mean low potential.

Temperature of electrodes.

The temperature at the two electrodes is, in general, very different. The true explanation of this difference has not been made out, although it is doubtless connected with the equally unexplained differences in the light phenomena. A general rule has been laid down, that the temperature of the negative electrode is always higher when the discharge takes place through the *gas* alone, and the temperature of the positive electrode higher when the discharges pass mainly through particles of disintegrated metal. The former case is commoner in vacuum tubes, where the negative electrode may get white hot, and even melt, while the positive electrode remains quite dark. The latter case is exemplified in the voltaic arc, in which great disintegration of the positive electrode is accompanied by a higher temperature there. Attempts have been made to investigate the temperature in different parts of the tube, and it seems to have been made out that the temperature is lower in the dark intervals than elsewhere.

Alternating discharges with inductorium.

When the electro-motor is an induction coil, which furnishes discharges alternately in opposite directions, there will be a mixture of positive and negative light at each electrode, unless the maximum tension corresponding to the inverse discharge be so small that the direct discharge alone can break through. If, however, the tube be examined by means of a rotating mirror, or if it be itself fastened to a rotating arm, the images of the different discharges will be separated, and it will be seen that the appearances at each electrode alternate.

With Leyden jar.

Again, when a Leyden jar is discharged through a vacuum tube, the appearances at the two electrodes are often very much alike, particularly when the resistance of the discharging circuit is very small. When the resistance is increased by introducing a column of water or lengths of wetted string, the appearances are similar to those indicated in our summary description. The reason of this is fully explained by the observations of Feddersen. He examined the spark of a Leyden jar by means of a rotating concave mirror. The machine which drove the mirror had a contact-maker, which brought on the discharge when the mirror was at a definite position; the image of the spark was thus thrown by the mirror on a piece of ground glass or a photographic plate, properly placed to receive it. He found that the discharge assumed three distinct characters as the resistance of the discharging circuit was gradually decreased.

Feddersen's results.

1. The discharge was *intermittent*, that is to say, consisted of a series of partial discharges all *in the same direction*, following each other at more or less irregular intervals.

2. When the resistance was reduced to a certain extent, the discharge became *continuous*. The image of the spark on the plate had then the form of an initial vertical strip, with two horizontal strips extending from each end, and gradually thinning off to a point. The vertical strip indicates a single initial spark, and the horizontal bands the finite duration of the light from the glowing metal particles, etc., near the electrodes.

3. When the resistance is very small, the discharge is *oscillatory, i. e.*, consists of a succession of discharges alternately *in opposite directions*. These oscillations are due to the self-induction of the discharging circuit; we shall examine the matter more carefully under Electro-magnetic Induction.

It is obvious that when the discharge is either *intermittent or continuous*, the luminous phenomena will be of the normal form sketched above, but when the discharge is *oscillatory* there will be a mixture of positive and negative appearances at each electrode, the independent existence of which cannot be detected by the unaided eye.

This is the place to remark that it is rarely that the discharge is of the simple form (2). *i. e.*, consists of a single continuous discharge; in by far the great majority of cases it consists of a series of partial discharges. With the inductorium, both varieties (1) and (3) may occur according to the length of the air-space, the resistance of the whole secondary circuit, and so on. A number of very beautiful experiments have been made to illustrate these principles, which it would take us beyond our limits to describe. Good summaries of the results of Felici, Cazin and Lucas, Donders and Nyland, Ogden Rood, and Alf. Mayer, will be found in Mascart and Wiedemann. Recent researches of a very important character have been made by Wüllner[1] and Spottiswoode[2] on the discharge in vacuum tubes. They employ the rotating mirror. It would be premature to attempt to sum up or criticise their results; suffice it to say that they show an amount of agreement which augurs well for the future of this branch of electrical science. The striæ seem, according to them, to play a more essential part in the phenomenon than was perhaps previously expected. Spottiswoode, in fact, seems to incline to the view that all discharges having a dark interval are really stratified, although, owing to their rapid motion, the strata may not be distinguishable by the eye alone.

Wheatstone's experiments. Velocity of electricity.

In connection with this subject it may be well to mention the early experiments of Wheatstone,[3] to determine the so-called velocity of electricity in conducting circuits. Six balls, 1, 2, 3, 4, 5, 6, were arranged in a straight line on a board; 2 and 5 were connected with the coatings of a charged Leyden jar; discharge passed by spark from 2 to 1, then through a large metallic resistance to 3, thence by spark to 4, then through a large metallic resistance to 6, and thence by spark to 5. It was found, as Feddersen observed later, that the introduction of the metallic resistance increased the duration of the sparks at all the intervals, so that the images in the mirror were *lines* of small length; but, in addition, the spark between 3 and 4 began a little later than the sparks at 1, 2 and 5, 6, which were simultaneous. From this the velocity of electricity has been calculated, by taking the interval[4] between the sparks to be *the time which the electricity takes to travel through the metal wire between the intervals.* Faraday long ago pointed out that this interval depends on the capacity of the wire, and may vary very much according to circumstances. It is very great in submarine telegraph wires for instance (*vide supra*, p. 36). Accordingly, the values of the so-called velocity of electricity, which have been found by different observers, differ extremely.

The sketch we have just given of the disruptive discharge in rarefied gases must be regarded as the merest outline. There are many points of great importance to which we have not even alluded. Hittorf's investigation on what has been called the "resistance" of different parts of a vacuum tube during the discharge has not been mentioned, although it led to results of much interest, which must come to be of great importance when the clue to an explanation of the whole phenomena has been found. The reader who desires to study the matter will find in Wiedemann an excellent account of Hittorf's work, with references to the original sources. We have not so much as raised the delicate and difficult questions concerning the spectroscopic characteristics of the discharge. A good part of this subject belongs indeed more properly to the science of Light.

Kinnersley's experiment.

Miscellaneous Effects, chiefly Mechanical.— Owing to the heat suddenly developed by the electric spark, and perhaps to a specific mechanical effect as well, there is a sudden dispersion in all directions of the particles of the di-electric. This commotion may be shown very well by means of Kinnersley's older form of the thermo-electrometer; or Gauss's instrument may be used if we replace the thin wire by a couple of spark terminals. When the spark passes, the liquid in the stem sinks suddenly through a considerable distance, even if the spark be of no great length (2 to 3 mm.).

Striæ from concussion.

Very curious effects are obtained when an electric spark is repeated several times at a little distance above a plate strewed with finely-powdered chalk. After a time the chalk is seen to be divided by a network of fine lines, resembling the markings on shagreen. If a plate of glass be covered with powdered charcoal, and the spark passed *through* the powder, it arranges itself in a series of striæ closely resembling those seen in a vacuum tube.

The power of the spark to induce chemical combination (in particular, combustion) is due no doubt mainly to its high temperature.

[2] *Proc. R. S.*, 1875–6, 7.

[3] *Phil. Trans.*, 1834.

[4] A better statement would be "the time that elapses before sufficient electricity has reached 3 and 4 to raise the tension at their nearest points to the disruptive limit."

Discharge in fluids.

The discharge through non-conducting liquids may take place in the form of spark or brush. The brush, however, is poor compared with that obtained in air, and is very hard to get. When the spark passes, pressure is suddenly transmitted through the fluid in all directions, and if it be inclosed in a tube the tube is generally broken, even when the spark is by no means long. When the surface of the liquid is free, a considerable portion is usually projected into the air. The convective discharge is very marked in liquids. If two small balls connected with the electrodes of a Holtz's machine in action be dipped in paraffin oil at a small distance apart, the whole liquid is thrown into violent motion by the convection currents, runs up the wires which lead to the balls, and spouts off in little jets.

There is also a distinct heaping up of the liquid between the balls, and if one of them be gradually withdrawn from the liquid, for a centimetre or so it raises a column after it, which adheres until the machine is stopped. It is very probable that other effects due to the alteration of the apparent surface tension, owing to the difference of electrical stress in the air and oil, are present in these phenomena, but this is hardly the place to discuss the matter.

The electric discharge passes with great facility through card-board and other bodies of loose texture. In all probability the air in such cases has quite as much to do with the resulting effects as the solid body.

Lullin's experiment.

A curious experiment of this kind is often made. Two points are arranged so as to touch the opposite sides of a piece of card-board. If the points be opposite each other, the discharge passes straight through, leaving in the case of small charges a tiny hole with burnt edges. If, however, the points be not opposite each other, the perforation occurs in the neighborhood of the negative point. The peculiarity is no doubt connected with those differences between positive and negative discharges in air which we have several times noticed above. In fact, it is found that in an exhausted receiver the card is pierced at a spot very nearly equidistant from the two points.

Discharge in solids.

In other cases the main part of the di-electric strength depends on the solid material. The power of such bodies to sustain the electrical tension is often very considerable. Yet there is a limit at which they give way. A thickness of 6 centimetres of glass has been pierced by means of a powerful induction coil.

In such experiments special precautions have to be taken to prevent the spark from gliding over the surface of the glass instead of going through; this is managed in some cases by embedding the glass along with the terminals of the coil in an electrical cement of considerable insulating power; in ordinary experiments, however, it is in general sufficient to place a drop of olive oil round one of the terminals where it abuts on the glass. The appearance of the perforations depends considerably on the quantity of electricity that passes in the discharge. In some cases the glass cracks or even breaks in pieces. In some large blocks we have seen a perforation in the form of several independent threads, each of which had a sort of beaded structure, which may possibly be in some way analogous to the stratifications in vacuum tubes.

Surface electrification.

Discharge along the Surface of a Body, Dust Figures, and Dust Images.—The class of phenomena referred to under this head are remarkable for the methods by which they are usually demonstrated. They were at one time much studied on account of the light they were supposed to throw on the nature of the so-called electric fluid or fluids. Though no longer regarded in this light, they have reference to an extremely important and comparatively little studied subject, viz., the distribution of electricity over the surface of non-conductors. It is easy to see that the demonstration of surface electrification on insulators is beset with difficulties of a peculiar kind. A very convenient method is to project on the surface a powder electrified in a known way; this powder clings to the parts oppositely electrified to itself, and avoids those similarly electrified, so that the state of the surface is seen at once. Lycopodium seed and powdered resin have been used in this way; they are sifted through linen cloth, the lycopodium becoming thereby weakly positive, and the powdered resin strongly negative. If the lycopodium be used, it covers both positive and negatively electrified patches, only the latter more thickly than the former. The powdered resin, on the other hand, covers the positive and avoids the negative regions. The most effective powder, however, is a mixture of flowers of sulphur[1] and red lead. In the process of sifting, the red lead powder becomes positively and the sulphur negatively electrified, and the powders separate themselves. The sulphur colors positive regions yellow, and the red lead colors negative regions red. The result is very striking; and the test is found to be very delicate.

Lichtenberg's figures, etc.

The dust figures of Lichtenberg are one of the best known instances of the kind of experiment indicated above. A sharp-pointed needle is placed perpendicular to a non-conducting plate, with its point very near to or in contact with the plate. A Leyden jar is discharged into the needle, and the plate is then tested with the powder. If the electricity communicated to the needle was positive, a widely extending patch is seen on the plate, consisting of a dense nucleus, from which branches radiate in all directions. If negative electricity was used, the patch is much smaller and has a sharp circular boundary entirely devoid of branches. This difference between the positive and negative figures seems to depend on the presence of the air; for the difference tends to disappear when the experiment is conducted in vacuo. Riess explains it by the negative electrification of the plate caused by the friction of the water vapor, etc., driven along the surface by the explosion which accompanies the disruptive discharge at the point. This electrification would favor the spread of a positive, but hinder that of a negative discharge. There is, in all probability, a connection between this phenomenon and the peculiarities of positive and negative brush and other discharge in air; Riess, indeed, suggests an explanation of the latter somewhat similar to the above.

There is another class of figures, to which Riess gives the name of electric images, of which the following may be taken as a type. A signet or other engraved piece of metal is placed on a plate of insulating material, and *steadily* electrified by means of a dry pile or otherwise positively or negatively for half an hour or so. When the metal is removed and the plate dusted, an exact figure of the stamp appears, consisting of a red or yellow background on which the engraved lines stand out free from dust. There is no difference between positive and negative electricity here as far as *form* is concerned, and the color of the figure indicates charge on the plate opposite to that on the metal. The phenomenon appears to be due simply to the electrification of parts of the non-conducting surface opposite the metal.

Figures of Karsten.

Another class of phenomena, to which Riess gives the name secondary, depend, not on the electrification of the surface, but on permanent alterations produced by the discharge, whether in the form of spark or otherwise. Sometimes these are directly visible to the eye or touch, *e.g.*, the roughening and discoloration which mark the path of the spark over a polished glass surface. In some cases they are chemical alterations, which may be shown by means of the proper reagents, *e.g.*, the separation of the potash in the spark traces on glass. In certain cases they become evident on breathing upon the glass; of this description are the images of Karsten. A piece of mirror glass is placed on an uninsulated metal plate, and on the glass is placed a coin or medal. Sparks are taken for some time between the coin and an electric machine, and then the glass plate is removed and breathed upon. A representation of the coin then appears on the glass, often complete to the smallest detail. The reader who is interested in these matters, historically or otherwise, will find a variety of information, with directions how to find more, in Riess's *Reibungselectricität*, Bd. ii. § 739 *sqq.*

Electro-magnetism and Electro-dynamics.[2]

Mention has already been made of the discovery of Oersted, that the electric current exerts a definite action on a magnetic needle placed in its neighborhood. This discovery formed the starting-point of that division of electrical science with which we are now to deal. It was natural, once the action of a current[3] on a magnet was observed, to look for the reaction of the magnet on the current, and after seeing two currents act on the same magnet, it was reasonable to expect that the currents would act on each other. Yet it may be doubted whether the first of these results is a legitimate deduction from the discovery of Oersted, and the second certainly is not so. Before we can apply the principle of the equality of action and reaction we must be quite certain of the source of the *whole* of any action to which the principle is to be applied. Again, two bodies A and C may act on B owing to properties acquired by virtue of B's presence, so that in the absence of B they need not necessarily act on each other. A good example is the case of two pieces of perfectly soft iron, each of which will act on and be acted on by a magnet, but which will not act on each other when the magnet is not near them.

---

[1] First used by Villarsy in 1788.

[2] Throughout this section the reader is supposed to be familiar with the experimental laws of magnetism (see art. MAGNETISM). If he desires fully to understand the mathematical developments that occur here and there, an occasional reference to the analysis used in the theory of magnetism will also be necessary, if he is not already familiar with it.

[3] "Current" is used here and in corresponding cases as an abbreviation for "the linear conductor conveying a current."

Ampère's relation to Oersted.

The questions thus raised by Oersted's discovery were experimentally settled by Ampère. He found that a magnet or the earth (which behaves as if it were a magnet) acts on the current, and the direction of these actions is found to be consistent with the principle of equality of action and reaction. As no experimental fact has yet been quoted against the application of this principle in such cases, we shall assume it henceforth. Ampère also discovered the action of one electric current on another, and thereby settled the second question. We may conclude, therefore, that the space surrounding an electric current is a field of magnetic force just as much as the space around a magnetized body.

The next step is to determine the distribution of magnetic force, or what amounts to the same thing, to find a distribution of magnetism which shall be equivalent in its magnetic action to the electric current. This also was completely accomplished by Ampère. In expounding his results we shall follow the order of ideas given by Maxwell,[1] which we think affords the simplest view of the matter, and is the best practical guide that we know of through the somewhat complicated relations to which the subject introduces us. We shall in addition give a sketch of the actual course which was followed by Ampère, and which is adhered to by the Continental writers of the present day.

Fundamental principle.

It results alike from the fundamental experiments of Ampère and the elaborate researches of Weber, to both of which we shall afterwards allude, that an electric current circulating in a small plane closed circuit, acts and is acted upon magnetically exactly like a small magnet placed perpendicular to its plane at some point within it[2], provided the moment of the magnet be equal to the strength of the current multiplied by the area of the circuit,[3] and its north pole be so placed that the direction of the axis of the magnet (from S-pole to N-pole), and the direction in which the current circulates are those of the translation and rotation of a right-handed (ordinary) screw which is being screwed in the direction of the axis. In this statement we have spoken of a *small* closed circuit. The word "small" means that the largest dimensions of the circuit must be infinitely smaller than its distance from the nearest magnet or electric current on which it acts, or by which it is acted on.

We may break up our small magnet into a number of similar magnets, and distribute them over the area of the small circuit, so that the sum of the moments of all the magnets on any portion w of the area is wi, where i is constant. We thus replace the circuit by a magnetic shell of strength i, which, if we choose, may be represented by two layers parallel to the area, one of north the other of south magnetism, the surface density of which is $i \div \theta$, where θ is the distance between the layers.[4]

Finite circuit and magnetic shell.

Starting from the principle thus laid down we can derive all the laws of the mutual action of magnets and electric currents.

Consider any finite circuit ABC (fig. 29). Imagine it filled with a surface of any form, and a network of lines drawn on the surface as in the figure, dividing it up into portions, such as *abcd*, so small that they may be regarded as plane. It is obvious that any current of strength i circulating in ABC may be replaced by a series of closed currents, each of strength i circulating in the meshes (such as *abcd*) of the network on the surface; for in each line such as bc we have two equal and opposite currents circulating whose action must be *nil*. Now, we may replace each of the small circuits by a magnet as above, or by a magnetic shell of strength i. The assemblage will constitute a magnetic shell of strength i filling up the circuit, whose magnetic action, at every point *external*[5] to the shell will be the same as that of the current. The north side of the shell is derived from the direction of the current by the right-handed screw relation given above.

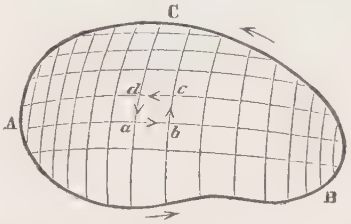

Fig. 29.

If dS be an element of the surface of a magnetic shell of strength i, D its distance from P, and θ the angle which the positive direction of magnetization (which is normal to dS) makes with D, then the magnetic potential[6] at P is given by

$$V = i\iint \frac{\cos\theta}{D^2} dS, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

the integration extending all over S.

When properly interpreted this double integral is found to represent the "solid angle" subtended at P by the surface S, or, as it may also be put, by the circuit ABC which bounds it. Hence, solid angles subtended by the north side being taken as positive, and the usual conventions as to sign adhered to, we may write

$$V = i\omega, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where ω is the solid angle in question.

Potential of shell.

We see, therefore, that the potential of a magnetic shell at any point P is equal to the product of the strength of the shell into the solid angle subtended by its boundary at P. Now the potential of such a shell is continuous and single-valued at all points without it. (With points within it we are not now concerned, since the action of the current at such points is not the same as that of the shell.) If, therefore, a unit north pole start from any point P and return to the same, after describing any path which does not cut through the shell, *i.e.*, does not embrace the current, the work done by it will be *nil*. Let us now examine what happens if the path cuts through the shell S. Take two points P and Q, infinitely near each other, but the one P on the positive side, the other Q on the negative side of the shell. In passing from P to Q, without cutting the shell, the solid angle ω decreases by 4π infinitely nearly. Now, during the passage from Q to P we may not represent the action of the current by S, but nothing hinders us from representing its action by another shell S′, which does not pass between Q and P, but is at a finite distance from either of them; for it will be remembered that the shell which represents the action of a current i is definite to this extent merely—that its strength is i, its boundary is the circuit, and it does not pass through the point at which the action is being considered. But infinitely little work, owing to the action of S′, is done in passing from Q to P. Hence the work done by a unit pole in going once completely round any path which embraces the current once is $4\pi i$.

To reconcile this result with the continuity of the magnetic potential of a linear circuit, for the existence of which we have now furnished sufficient evidence, we must admit that the potential of a linear circuit at any point P is $V = i(\omega + 4n\pi)$, where n is any integer. In other words, V is a many-valued function differing from i times the solid angle subtended at P by a multiple of $4\pi i$. If we pass along any path from P and return thereto, the difference of the values of V, or the whole work done on the journey, is zero if the path does not embrace the circuit, $4n\pi i$ if it embraces[1] it n times.

---

[1] *Electricity and Magnetism*, vol. ii. §§ 475, etc.

[2] Naturally the centre of the area if it is symmetrical.

[3] We shall see directly what system of units this statement presupposes.

[4] The reader who finds difficulty with the magnetic shell may adhere to the small magnet; it will be found sufficient for most practical purposes.

[5] This limitation is the equivalent of the limitation *small* applied to the elementary plane circuit, and follows therefrom.

[6] We need scarcely remind the reader that all the definitions of potential, etc., in the theory of electro-statics apply here if we substitute + and — magnetism for + and — electricity. The unit of + magnetism is sometimes called a unit north pole.

Linear circuit in magnetic field.

The considerations enable us to determine the action of any closed current on a magnetic pole, and consequently on any magnetic system. We have next to find the action on a linear circuit when placed in any given magnetic field, whether due to magnets or electric currents. This we do by replacing the circuit acted on by its equivalent magnetic shell.

If the potential at any point of the magnetic field be V, then the potential energy of a magnetic shell S, of strength i, placed in the field is given by

$$M = i\iint\left(l\frac{dV}{dx} + m\frac{dV}{dy} + n\frac{dV}{dz}\right)dS, \quad . \quad . \quad (3)$$

where (l, m, n) are the direction cosines of the positive direction (south to north) of the normal to the element dS. Since, so long as the magnetic force considered is not due to S itself, there is none of the magnetism to which V is due on S, we may write $-a, -b, -c$ for $\frac{dV}{dx}, \frac{dV}{dy}, \frac{dV}{dz}$, where a, b, c are the components of the magnetic induction.[2] Then, if $N = \iint(la + mb + nc)dS$ (*i.e.*, = the surface integral of magnetic induction, or the number of lines of magnetic force which pass through the circuit), we may write

$$M = -iN \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

From this expression for the potential energy of the equivalent magnetic shell we can derive at once the force tending to produce any displacement of the circuit regarded as rigid.

Thus let ϕ be one of the variables which determine the position of the system, then the force Φ tending to produce a displacement $d\phi$ is given by $\Phi d\phi + dM = 0$, or

$$\Phi = i\frac{dN}{d\phi} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Hence the work done during any displacement of a closed circuit, in which the current strength is i, is equal to i times the increase produced by the displacement in the number of lines of force passing through the circuit. The force tends, therefore, to produce the displacement or to resist it, according as the displacement tends to increase or to diminish the number of lines of force passing through the circuit. It is evident, therefore, that a position of stable equilibrium will be that in which the number of lines of magnetic force passing through the circuit is a maximum. If that number is a minimum, we have a case of unstable equilibrium.

Action on element of circuit.

Maxwell[3] has shown how we may deduce from the above theory the force exerted on any portion of the circuit which is flexible or otherwise capable of motion. "If a portion of the circuit be flexible, so that it may be displaced independently of the rest, we may make the edge of the shell capable of the same kind of displacement by cutting up the surface of the shell into a sufficient number of portions connected by flexible joints. Hence we conclude that, if by displacement of any portion of the circuit in a given direction the number of lines of induction which pass through the circuit can be increased, this displacement will be aided by the electro-magnetic force acting on the circuit."

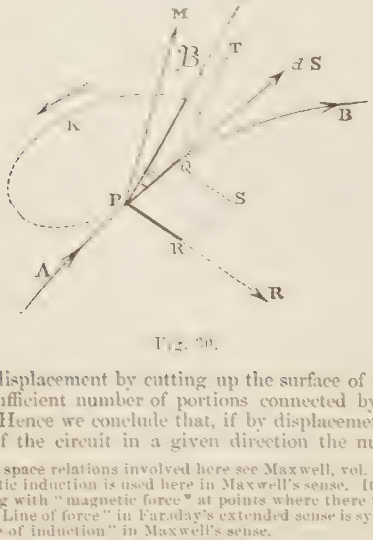

Fig. 30.

From these considerations we may find the electro-magnetic force acting on any element ds of the circuit. Let PQ (fig. 30) be the element ds belonging to the arc AB of any circuit. Let P$\mathfrak{B}$ be the direction of the magnetic induction[4] at P, and $\mathfrak{B}$ its magnitude. It is obvious that no motion of PQ in the plane of PQ and P$\mathfrak{B}$ will increase or diminish the number of lines of force passing through the circuit; consequently no work will be done in any such displacement. Hence the resultant electro-magnetic force R must be perpendicular to the plane QP$\mathfrak{B}$. Let PR be a small displacement perpendicular to this plane, the work done in the displacement is R.PR, and the number of lines of force cut through is i times the rectangular area PQR multiplied by the component $\mathfrak{B}\sin\theta$ of the magnetic induction perpendicular to it. Hence we have

$$R \times PR = ids \times PR \times \mathfrak{B}\sin\theta,$$

i.e.,

$$R = ids\mathfrak{B}\sin\theta \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

Hence the resultant electro-magnetic force on the element ds may be determined as follows:—Take P$\mathfrak{B}$ in the direction of the resultant magnetic induction (magnetic force) and proportional to $i\mathfrak{B}$, and take PQ in the direction of ds and proportional to it; the electro-magnetic force[5] on the element of the circuit is proportional to the area of the parallelogram whose adjacent sides are P$\mathfrak{B}$ and PQ, and is perpendicular to it. The force in any direction making an angle ϕ with the direction of the resultant is of course $R\cos\phi$. The following consideration is convenient for determining which way the resultant force acts. It is obvious that the force on the element will be the same to whatever circuit we suppose it to belong, so long as the direction and strength of the current in it are the same. Take, then, a small circuit PQK perpendicular to the lines of magnetic induction (magnetic force) near PQ, in such a way that the direction of the current in PQK (as determined by the direction in PQ) is related to the direction of the magnetic induction in the same way as rotation and translation in right-handed screw motion; then the element PQ tends to move so that the number of lines of force passing through PQK increases.[6]

Several other ways of remembering this direction might be given. Although the above may sound arbitrary and look clumsy at first, yet we have found it more convenient in practice than some others we have tried.

We may extend what has been said above to the case where part of the magnetic force, it may be the whole of it, is due to the current in the circuit itself; for we might suppose the magnetic field to be that due to a shell whose boundary coincides infinitely nearly with the circuit. If the circuit is rigid, there will of course be no motion caused by its own action; but if it be flexible, there may be relative motions; in fact each portion will move until the number of lines of force that pass through the circuit is the greatest possible consistent with the geometrical conditions.

Vector potential, etc.

It is an obvious remark, after what has been said, that the potential energy of the magnetic shell which represents a current depends merely on its boundary, or, in other words, that the magnetic induction or the number of lines of magnetic force which pass through a circuit depends merely on its form. Hence we should expect to find some analytical expression for the surface integral of magnetic induction depending merely on the space relations of the circuit; in other words, we should expect to find a line integral to represent it. And when the field is that of another circuit, we should expect to find a double line integral for the mutual potential energy of the two representative shells.[7] We shall describe briefly how these expectations are realized.

In the first place, a vector may be found which has the property that its line integral taken round any circuit is equal to the surface integral of magnetic induction taken over any surface bounded by the circuit.[1] This vector has been called by Maxwell the "vector potential" ($\mathfrak{A}$). Let its components be F, G, H. Then applying the definition to small areas, $dydz$, $dzdx$, $dxdy$, at the point xyz perpendicular to the three axes,[2] a, b, c being components of magnetic induction as before, we get

---

[1] On the space relations involved here see Maxwell, vol. i. § 17, etc.

[2] Magnetic induction is used here in Maxwell's sense. It coincides in meaning with "magnetic force" at points where there is no magnetism. "Line of force" in Faraday's extended sense is synonymous with "line of induction" in Maxwell's sense.

[3] *Electricity and Magnetism*, vol. ii. § 490.

[4] "Resultant magnetic force," if there is none of the magnetism producing it at P.

[5] We need scarcely remind the reader that this is a pondero-motive force acting on the matter of the element of the circuit. There is no question of force acting on the current or the electricity in it.

[6] From this may be derived the following, which is often very convenient. Stand with feet on PQ and body along the positive direction of the line of magnetic force and look in the direction of the current, then the force is towards the right hand.

[7] It is important to remark here that we say "of the two representative shells" not "of the two circuits," or "of the two currents" (see below, p. 72).

$$a=\frac{dH}{dy}-\frac{dG}{dz},\quad b=\frac{dF}{dz}-\frac{dH}{dx},\quad c=\frac{dG}{dx}-\frac{dF}{dy}\ .\ .\ (7)$$

These equations might be used to determine F, G, H, and would lead to a much more general solution than is here required. The following synthetical solution is simpler.

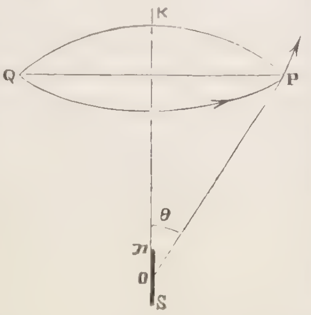

Fig. 31.

Consider a magnetized particle sn at O (fig. 31). Let the positive direction of its axis be OK, and let its moment be m. The resultant force due to sn at any point P is in a plane passing through OK; hence the vector potential $\mathfrak{A}$ at P must be perpendicular to this plane. Let its direction be taken so as to indicate a rotation round OK, which with translation along OK would give right-handed screw motion. Describe a sphere with O as centre and OP ($=$ D) as radius. Let PQ be a small circle of this sphere whose pole is K. Consider the line integral round PQ, and the surface integral over the spherical segment PKQ. Since $\mathfrak{A}$ is the same at all points of PQ by symmetry, the former is $2\pi D\sin\theta\mathfrak{A}$, and the latter is $\frac{2\pi m\sin^2\theta}{D}$. Equating these we get for vector potential of sn at P,

$$\mathfrak{A}=\frac{m}{D^2}\sin\theta,\ .\ .\ .\ .\ .\ .\ (8)$$

its direction being that already indicated.

Suppose now the particle sn placed at Q(xyz) so that the direction cosines of sn are λ, μ, ν. Let the co-ordinates of P be ξ, η, ζ; also let $QP=D=+\sqrt{(\xi-x)^2+(\eta-y)^2+(\zeta-z)^2}$. Then the direction cosines of QP are $D^2\frac{dp}{dx}$, $D^2\frac{dp}{dy}$, $D^2\frac{dp}{dz}$, where $p=\frac{1}{D}$; and we get for the component of the vector potential at P

$$F=m\left(\mu\frac{dp}{dz}-\nu\frac{dp}{dy}\right),\ .\ .\ .\ .\ .\ .\ (9)$$

and two similar expressions for G and H.

Expression for vector potential.

The vector potential of a magnetized body may be got by compounding the vector potentials of the different elements; hence Iλ, Iμ, Iν being the components of magnetization at any point of the body, we get

$$F=\iiint I\left(\mu\frac{dp}{dz}-\nu\frac{dp}{dy}\right)dxdydz,\ .\ (10)$$

and two similar expressions for G and H. The first part of our problem is thus solved.

Let us, in the second place, apply the above result (10) to the case of the two shells which are equivalent to two currents. In a *lamellar* distribution of magnetism $\frac{d(I\mu)}{dz}=\frac{d(I\nu)}{dy}$, etc.: hence the volume integral in (10) reduces to a surface integral, and

$$F=\iint\frac{1}{D}I(\mu n-\nu m)dS,\ .\ .\ .\ .\ (11)$$

where l, m, n are the direction cosines of the outward normal to dS.

Now the magnetic shell of thickness τ and strength i is a lamellarly magnetized body of constant intensity $=i\div\tau$. It may be looked upon as bounded by two parallel surfaces normal everywhere to the lines of magnetization, and by an edge generated by lines of magnetization. At every point on either of the parallel surfaces we have therefore $l=\lambda$, $m=\mu$, $n=\nu$; and at the edge $l=\nu\frac{dy}{ds}-\mu\frac{dz}{ds}$, and similarly for m and n. Hence every element of the double integral in (11) belonging to either of the parallel surfaces vanishes, and there remain only the parts on the edge which give

$$F=\Sigma\frac{I\tau}{D}\left\{\mu\left(\mu\frac{dx}{ds}-\lambda\frac{dy}{ds}\right)-\nu\left(\lambda\frac{dz}{ds}-\nu\frac{dx}{ds}\right)\right\}ds=$$
$$i\int\frac{1}{D}\frac{dx}{ds}ds,\ .\ .\ .\ .\ .\ .\ .\ (12)$$

since $\lambda\frac{dx}{ds}+\mu\frac{dy}{ds}+\nu\frac{dz}{ds}=0$. (12) gives the vector potential at ($\xi\eta\zeta$) due to a magnetic shell S. Let ($\xi\eta\zeta$) be any point on the boundary of another shell S, of strength i, and let $d\sigma$ be the element of arc of the boundary, then

$$-i'\int\left(F\frac{d\xi}{d\sigma}+G\frac{d\eta}{d\sigma}+H\frac{d\zeta}{d\sigma}\right)d\sigma\ .\ \ .\ \ .\ (13)$$

is the magnetic induction through S′ due to S with the sign changed, in other words, the mutual potential energy M. Putting for F, G, H their values by (12) we have

Double line integral for M.

$$M=-ii'\iint\frac{1}{D}\left(\frac{dx}{ds}\frac{d\xi}{d\sigma}+\frac{dy}{ds}\frac{d\eta}{d\sigma}+\frac{dz}{ds}\frac{d\zeta}{d\sigma}\right)dsd\sigma$$
$$=-ii'\iint\frac{\cos\epsilon}{D}dsd\sigma,\ .\ .\ .\ .\ .\ .\ .\ .\ .\ .\ (14)$$

where ϵ is the angle between ds and $d\sigma$.

The result of (14) realizes the second of our expectations. The double integral arrived at is of great importance, not only in the theory of electro-dynamics, but also as we shall see in the theory of the induction of electric currents.

Ampère's law deduced.

Hitherto we have spoken only of closed circuits, and considered merely the action of a circuit regarded as a whole. When we did speak of the force on an element of a circuit, we deduced this force directly from the state of the magnetic field in its immediate neighborhood. There is an order of ideas, however, in which the mutual action of two circuits is considered to be the sum of all the mutual actions of every element in one circuit on every element in the other. Now, we can easily show, by means of (14), that a system of elementary forces of this kind can be found which will lead to the same result for closed circuits as the theory given above.

Let the circuit S′ be supposed rigid and fixed, and let the circuit S be movable in any way with respect to S′; it may even be flexible. Denote the angles between the positive directions of $d\sigma$ and ds and the direction of D from $d\sigma$ to ds by θ' and θ, then we have

$$\left.\begin{array}{l}\cos\theta=\frac{dD}{ds},\ \cos\theta'=-\frac{dD}{d\sigma},\\ \cos\epsilon=-\frac{dD}{ds}\frac{dD}{d\sigma}-D\frac{d^2D}{dsd\sigma}\end{array}\right\}\ .\ .\ .\ (15)$$

By means of these we get

$$M=ii'\iint\frac{1}{D}\frac{dD}{d\sigma}\frac{dD}{ds}d\sigma ds.\ \ .\ \ .\ \ .\ (16)$$

The part which is a complete differential has been left out, because it disappears when the integration is carried round closed circuits, as we always suppose it to be. Consider now the work done in a small displacement which alters D and S, $\frac{dD}{d\sigma}$, $\frac{dD}{ds}$, and ds, but not $d\sigma$; we have

$$\delta M=-ii'\iint\frac{1}{D^2}\frac{dD}{d\sigma}\frac{dD}{ds}\delta Dd\sigma ds+ii'\iint\frac{1}{D}\frac{d\delta D}{d\sigma}\frac{dD}{ds}d\sigma ds$$
$$+ii'\iint\frac{1}{D}\frac{dD}{d\sigma}\left(\frac{d\delta D}{ds}-\frac{dD}{ds}\frac{d\delta s}{ds}\right)d\sigma ds$$
$$+ii'\iint\frac{1}{D}\frac{dD}{d\sigma}\frac{dD}{ds}\frac{d\delta s}{ds}d\sigma ds.$$

The parts containing δs disappear in this expression, and if the rest be arranged by integration by parts as usual, we get

$$\delta M-\iint R\delta Ddsd\sigma=0,\ \ .\ \ .\ \ .\ \ .\ (17)$$

where $R=ii'\frac{2\cos\epsilon-3\cos\theta\cos\theta'}{D^2}$.

Hence the electro-dynamical action of the two circuits is completely accounted for by supposing every element $d\sigma$ to *attract* every element ds with a force

$$\frac{ii'dsd\sigma}{D^2}\left(2\cos\epsilon-3\cos\theta\cos\theta'\right).\ \ .\ \ .\ (18)$$

---

[1] The mathematical idea concerned here seems to have been originally started by Prof. Stokes; it is deeply involved in the improvements effected in the theories of hydro-dynamics, elasticity, electricity, etc., by Stokes, Thomson, Helmholtz, and Maxwell.

[2] It is to be noted that the rectangular axes here used are drawn thus:—ox horizontal, oz vertical (in plane of paper say), and oy from the reader; thus— 
In this way rotation from y to z and translation along ox give right-handed screw motion, and so on in cyclical order.

We may therefore use this elementary formula whenever it suits our convenience to do so.

Action on magnetic pole.

It is very easy to obtain a similar elementary formula, which is very often useful, for the action of an element of a circuit on a unit north pole.

We have seen above how to find the action on an element PQ (ds) of a circuit in a given magnetic field. Let the field be that due to a unit north pole N (fig. 32). Then the magnetic induction at P is in the direction NPK, and is equal to $\frac{I}{D^2}$, if NP = D. Hence by (6) the force R on PQ[1] is perpendicular to NP and PQ, is in the direction PM shown in the figure, and is equal to $\frac{ids\sin\theta}{D}$. Now, by the principle of "action and reaction," the force on N is R in the direction PM′ opposite to PM, *i.e.*, is equal to a force R acting at N in a direction NM″ parallel to PM′, together with a couple whose moment is R × PN, and whose axis is perpendicular to NP and in the plane NPQ. Now a simple calculation, which we leave to the reader, will show that for any closed circuit the resultant of all the couples thus introduced is *nil;* hence, since we deal with closed circuits only, we may neglect the couple.

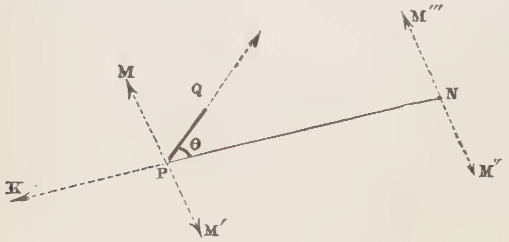

Fig. 32.

The force exerted by a closed circuit on a unit north pole may therefore be found by supposing each element ds to act on the pole with a force equal to

$$\frac{ids\sin\theta}{D^2}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (19)$$

whose direction is perpendicular to the plane containing the pole and the element, and such that it tends to cause rotation round the element related to the direction of the current in it by the right-handed screw relation.

Agreement of theory with experience.

Comparison of Theory with Experiment.—The best verification of the theory which has just been laid down consists in its uniform accordance with experience. We proceed to give a few instances of its application, adopting now one, now another, of the equivalent principles deduced from it.

Straight current.

We have already remarked that the lines of magnetic force in an electric field due to an infinite straight current are circles having the current for axis. It is easy to deduce from the fact that there is a magnetic potential that the force must vary inversely as the distance from the current.

This may also be proved by means of the formula (19); in fact, the resultant force at P is given by

$$R = i\int\frac{\sin\theta}{D^2}ds = i\int_0^\pi\frac{\sin\theta}{d^2\operatorname{cosec}^2\theta}\operatorname{cosec}^2\theta d\theta = \frac{2i}{d}, \quad . \quad (20)$$

d being the distance of P from the current.

Parallel currents.

Let AB (fig. 33) be a very long straight current, and poq an element ds of a parallel current, having the same direction as AB. If we draw the line of force (a circle with C as centre) through O, the tangent $\overrightarrow{OR}$ is the direction of the force at O; hence by (6) and (20), the force on poq is $\frac{2i}{d}ds$, and acts in the direction OC; poq is therefore attracted. If the current in poq be reversed, the force will have the same numerical value, but will act in the direction CO. Hence two parallel straight conductors attract or repel each other according as the currents in them have the same or opposite directions.

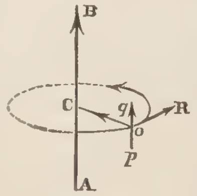

Fig. 33.

Inclined currents.

Let $\overrightarrow{AB}$ (fig. 34) be an infinitely long (or very long) current, $\overrightarrow{CD}$ a portion of a current inclined to it, and passing very near it at O. If the plane of the paper contain AB and CD, then at every point in OD the magnetic force is perpendicular to the plane of the paper and towards the reader, at every point in OC perpendicular to the plane of the paper and from the reader; hence at the elements P and Q the forces acting will be in the direction of the arrows in the figure, and CD will tend to place itself parallel to AB. If both the currents be reversed, the action will be unaltered; but if the current in CD alone be reversed, it will move so that the acute angle DOB increases. Hence it is often said that currents that meet at an angle attract each other, when both flow to or both flow from the angle, but repel when one flows to and the other flows from the angle.

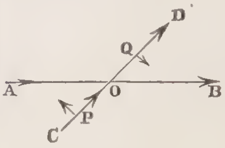

Fig. 34.

Ampère's apparatus.

These actions may be demonstrated in a great variety of ways. Figure 35 shows an arrangement for demonstrating the attraction or repulsion of parallel currents, which is essentially that first used by Ampère. A is an upright consisting of a tube in good metallic connection with one of the binding screws t, and with a little cup p, containing a drop of mercury. A stout wire passes up the centre of the tube, and is insulated from it, but in metallic connection with the screw s and the cup q. B is a light-conductor,[2] consisting of two parallelograms of wire, in which the current circulates in opposite directions, the object of which is to eliminate the magnetic action of the earth. The conductor is hung in the cups p and q, so as to be easily movable about a vertical axis. C is a frame on which several turns of wire are wound, so that when a current is passed through, we have a number of parallel conductors, all of which act in the

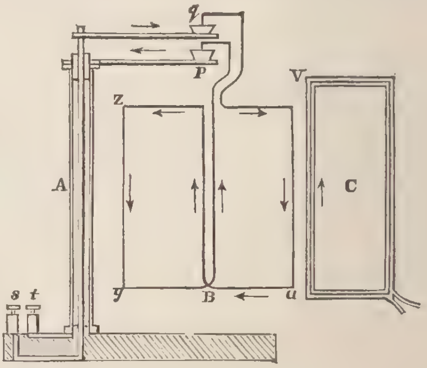

Fig. 35.

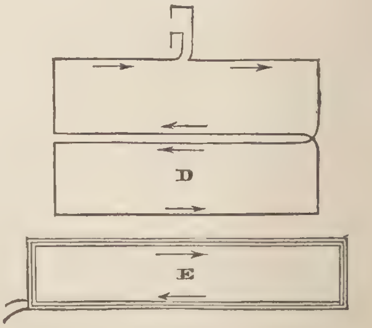

Fig. 36.

---

[1] PQ is supposed to be drawn *from* the reader.

[2] Aluminium is often used.

same way on the vertical branch uv of the movable conductor. Owing to the opposite directions of the currents in the tube and the wire inside it, there is no action on yz due to that part of the apparatus. It is clear, therefore, that the action of C on uv will prevail and determine the motion.

The action of straight conductors, making an angle with each other, may be shown by means of the conductor D, represented in fig. 36, which may be fitted to the stand shown in fig. 35.

Circular circuit.

In a very large class of practical cases, circular circuits play an important part. The most convenient way of dealing with these, as a rule, is to replace them by the equivalent magnets or magnetic shells. The action of a circular circuit may be represented by two layers of north and south magnetism, whose surface densities are $\pm\ i \div \tau$, where i is the strength of the current and τ the distance between the layers. For details concerning the calculations in a variety of cases, we refer the reader to Maxwell's *Electricity and Magnetism*, vol. ii. cap. xiv.

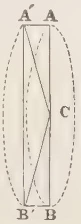

Fig. 37.

We may calculate the force exerted (see fig. 37) by a circular current AB on a unit north pole at its centre C, as follows. Replace the current by two discs AB and A′B′, of north and south magnetism, the distance between which is τ; the surface densities are $+\ i \div \tau$ and $-\ i \div \tau$. The first of these exerts a repulsive force $2\pi i \div \tau$, the second an attractive force

$$2\pi i \div \tau(1 - \cos\tfrac{1}{2}A'C'B')\,;$$

hence the resultant repulsive force is

$$2\pi i \cos\tfrac{1}{2}A'C'B' \div \tau = 2\pi i \div r,$$

r being the radius of the disc. Hence a unit of length of the current exerts a force $i \div r^2$ at the distance r.

Unit of current strength.

It follows therefore that the statement of our fundamental principle (p. 63) involves a unit of current strength such that unit length of the unit current, formed into an arc whose radius is the unit of length, exerts a unit of force on a unit pole placed at the centre of the arc. From this statement and the definition of a unit negative pole it follows at once that the dimension of the unit of current is $[L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}]$.

Solenoid.

One arrangement of circular currents has become famous from the part it plays in Ampère's theory of magnetism. A wire wound into a cylindrical helix, such as that represented in figure 38, the ends of the wire being returned parallel to the axis of the helix, and bent into pivots, so that it can be hung upon Ampère's stand (fig. 35), is called a solenoid. The conductor thus formed is obviously equivalent to a series of circular currents disposed in a uniform manner perpendicular to a common axis. In the case represented in figure 38, this axis is straight; but the name solenoid is not restricted to this particular case, and what we are about to advance will apply to a solenoid whose axis is a curve of any form.

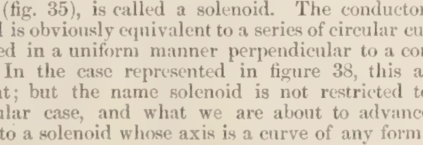

Fig. 38.

Let there be nds of the circular currents (each of area λ) in the arc ds of the axis of the solenoid. As we suppose the distribution to be uniform, n is constant. We may suppose each current to be placed at the middle of a length $\frac{1}{n}$ of the axis, which it occupies for itself. Hence, if each circular current be replaced by a shell of thickness $\frac{1}{n}$, the surface densities of the magnetism on each of these shells will be $\pm\ ni$, and the north magnetism of each shell will coincide with the south magnetism of the next; so that the whole action *at points external to the solenoid* reduces to the action of a quantity $ni\lambda$ of magnetism spread over one end of the solenoid, and a quantity $-\ ni\lambda$ spread over the other. The positive or north end of the solenoid is obtained, as usual, from the direction of the current, by means of the right-handed screw relation. If λ be very small, or if the system acting on, or acted upon by, the solenoid is at a distance very great compared with the dimensions of λ, then we may suppose the representative magnetism concentrated at the ends of the axis of the solenoid.

Hence the particular arrangement of electric currents, which we have called a solenoid, acts and is acted on exactly like an ideal linear magnet (whose poles coincide with the ends of its axis).

Thus the north pole of a magnet or solenoid repels the north end and attracts the south end of a solenoid; a solenoid tends to set under the action of the earth, its north end behaving like a magnetic north pole, and so on.

Cylindrical bobbin.

In a cylindrical bobbin wound to a uniform depth with silk-covered wire we have an arrangement which is equivalent to a number of solenoids all having a common axis. Each of these solenoids may be replaced by the equivalent terminal discs of positive and negative magnetism, and the external action of the whole thus calculated. The magnetic disc at each end will, of course, not be of uniform density,[1] but if the points acted on be at a distance which is infinitely great compared with the lateral dimensions of the bobbin, we may collect the magnetism at the ends of the axis; the quantities will be

$$\pm\ mni\frac{\pi}{3}(a^2 + ab + b^2),$$

where a and b are the outer and inner radii of the shell of wire, m the number of layers in the depth, and n the number of turns per unit of length of each layer. The magnetic moment of the bobbin is therefore

$$mpi\frac{\pi}{3}(a^2 + ab + b^2),$$

where p denotes the number of turns in each layer, and mp the whole number of turns on the bobbin.

Weber's experiments. Electro-dynamometer.

The above is a simple case of the kind of calculation on which Weber founded his verification of Ampère's theory. He did not, however, replace the circular currents by the equivalent magnetic distributions, but calculated directly from Ampère's formula (18).

The instrument (electro-dynamometer) which he used in his experiments was invented by himself. It consists essentially of a fixed coil and a movable coil, usually suspended in the bifilar manner, and furnished with a mirror, so that its motions about a vertical axis can be read off in the *subjective* manner (see art. GALVANOMETER) by means of a scale and telescope. Two varieties of the instrument were used by Weber. In one of these (A), the movable coil was suspended within the fixed coil; in the other (B), the movable coil was ring-shaped, and embraced the fixed coil, which, however, was so supported that it could be arranged either inside the movable coil or outside it at any distance and in any relative position with respect to it. We do not propose to go into detail respecting Weber's experiments, but merely to indicate their general character and give some of the results. Those desiring further information will find it in §§ 1–9 of the *Electro-dynamische Maasbestimmungen.*

Weber first showed that the electro-dynamic action between two parts of a piece of apparatus traversed by the same current varies as the square of the current. Apparatus A was arranged with the plane of its fixed coil in the magnetic meridian. The movable coil was concentric with the fixed one, but its plane was perpendicular to the magnetic meridian. The current of 1, 2, or 3 Grove's cells was sent through the fixed coil and through the suspended coil; but as the deflection with this arrangement was too great, the latter was shunted by connecting its terminals by a wire of small but known resistance. A measurement of the *first power* of the strength of the current was found by observing the deflection produced by the current in the fixed coil on a magnet suspended in its plane at a convenient distance north of it. After the necessary corrections were applied, the following results were obtained :—

n	D	M	M′	Diff.
3	440·038	108·426	108·144	− 0·282
2	198·255	72·398	72·589	+ 0·191
1	50·915	36·332	36·786	+ 0·454

---

[1] The reader will easily find the law for himself.

where n is the number of cells, D the electro-dynamic force on the suspended coil, expressed in an arbitrary unit, M the force on the magnet, M′ the force on the magnet calculated from $\sqrt{D}$ by means of a constant multiplier. The agreement between M and M′ is within the limits of experimental error.

In another series of experiments Weber used the apparatus B described above. The suspended coil was arranged with its axis in the magnetic meridian, and the fixed coil set up with its axis perpendicular to the magnetic meridian. Experiments were made with the centres of the two coils coincident, and with the centres in the same horizontal plane, at distances of 300, 400, 500, and 600 millimetres, the fixed coil being, in one set of experiments, east or west from the suspended coil; in another set, north or south. In the present series of experiments the strength of the current was measured by means of a magnet acted on, not by the fixed coil, but by another coil in circuit with it. After proper corrections, the following results were arrived at:—

d	P	P′	Q	Q′
0	22960	22680	22960	22680
300	189·93	189·03	77·11	77·17
400	77·45	77·79	34·77	34·74
500	39·27	39·37	18·24	18·31
600	22·46	22·64	. . .	. . .

where d is the distance between the centres of the coils, P the couple[1] exerted on the movable coil when the direction of that distance is perpendicular to the meridian, Q the couple when it is in the meridian. P′ and Q′ are the values of the same couples calculated from the theory of Ampère. The agreement here again is as near as could be expected.

Weber further showed that the deflections (v, w) of the suspended coil, calculated by means of the formulæ

$$\tan v = ad^{-3} + \beta d^{-5}$$
$$\tan w = \tfrac{1}{2}ad^{-3} + \gamma d^{-5}$$

in the two cases where the centres of the coils were at a considerable distance apart, agreed with observation within the limits of experimental error. Now these formulæ are identical with those established by Gauss for two magnets with their axes placed like the axes of the coils. This agreement therefore is an experimental proof that the coils are replaceable by magnets.

On the whole, therefore, the experiments of Weber[2] confirm the theory of Ampère, as far as experiment can test it. They form, therefore, a sufficient basis for the proposition on which we founded our theory; for this proposition leads to the same result for closed circuits as the theory of Ampère.

Experiments of Biot and Savart.

The action of any current on a magnetic pole, and hence on any magnet, may be calculated either by replacing the circuit by an equivalent shell or by means of formula (19). We have already found this action in the particular case of an infinitely long straight current. This result was originally found experimentally by Biot and Savart, and Laplace showed that it followed from their result that the force exerted by an element of the current varies inversely as the square of the distance. The fact that a circular current acts on a magnetic pole at its centre in the same way as a zig-zag current which is everywhere very nearly coincident with it, leads, when properly interpreted, to the conclusion that the force varies as sin θ. In this way formula (16) was originally arrived at, independently of Ampère's theory.

Earth's action.

A great variety of instances might be given of the action of a magnet on a current. The earth, for instance, acts on a circular current, hung up on Ampère's stand: the current, being movable about a vertical axis, will turn until the maximum number of the earth's lines of magnetic force pass through it—*i. e.*, it will set with its plane perpendicular to the magnetic meridian, in such a way that the current, looked at from the north side, goes round in the opposite direction to the hands of a watch.

De la Rive's floating battery.

A very simple way of showing the action between magnets and currents was devised by De la Rive. A small plate of copper and a small plate of zinc are connected together by a wire passing through a cork and making a circuit of several turns; the cork is placed in a vessel containing dilute sulphuric acid, and floats on the surface, carrying the little circuit about with it. Such a circuit will set under the earth's action, and may be chased and turned about, etc., by a magnet. After what has been already said, however, such experiments offer no new point of interest.

On rotations in general.

Electro-magnetic Rotations.—It is obvious that no invariable system of electric currents can produce continuous rotation of a magnetized body. For, suppose an elementary magnet, whose action may be represented by two poles of strengths $\pm\ m$, to describe any path and to return exactly to its former position; either it has or has not embraced the circuit in its path; if it has not, no work has been done on either pole; if it has embraced the circuit n times, an amount of work $4nm\pi i$ has been done on the north pole, and an amount $-4nm\pi i$ on the south; on the whole, therefore, no work has been done on the magnet. As any magnetized body may be conceived to be made up of such elementary magnets, it is obvious that it is impossible for such a body to rotate continuously, doing work against friction,[3] etc.

The same is obviously true if we replace the magnet by an invariable system of electric currents.

If, however, part of the electric circuit is movable with respect to the rest, and communicates therewith by means of sliding contacts or the like, continuous rotation of part of the circuit may occur. Again, if by any artifice the magnet can be transferred every revolution from one side of the current to the other, continuous rotation of the magnet may result. Lastly, if the direction of the current in some part of the apparatus be always reversed at a certain stage of the revolution, continuous motion may ensue.

Faraday's apparatus.

Rotations of the first and second class were first discovered by Faraday, and the ground principle of most of the pieces of apparatus used in demonstrating them is that originally used by him.

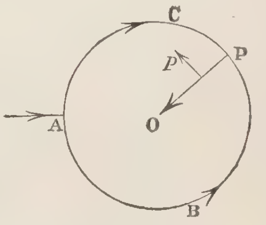

Fig. 39.

One of the simplest cases is the rotation under the action of the vertical component of the earth's magnetic force. Let ABC (fig. 39) be a horizontal circular conductor, OP a conductor pivoted at O, having sliding contact at P with ABC. Let a current i enter ABC at A, and leave it at P, flowing through PO to O and thence to the battery again. The magnetic force at any element dr of OP is perpendicular to OP and to the plane of ABC, hence the electro-magnetic force on the element will be in the plane of ABC, in the direction of the arrow p,[4] and will be equal to $i\mathrm{R}dr$ (R = vertical component of earth's force). Hence the moment about O of the forces acting on OP is $\int i\mathrm{R}r\,dr$, *i. e.*, $\tfrac{1}{2}\mathrm{OP}^2\mathrm{R}i$, which is independent of the position of OP. OP will therefore rotate about O, with an angular velocity which will go on increasing until the work lost by friction, etc., during each revolution is equal to $\pi\mathrm{OP}^2\mathrm{R}i$.

Ampère's theory.

Ampère has given a general theory of the rotation of a circuit under the action of a magnet. Let AB (fig. 40) be any circuit, which we may suppose connected with the axis of the magnet, but free to rotate about it. We suppose the magnet replaced by quantities $\pm m$ of magnetism at its poles. Take the axis of the magnet for axis of z, and the other axes as in the figure, O being the centre of the magnet, and let ON = OS = c. Let PQ be any arc ds of AB, and let the co-ordinates of P be

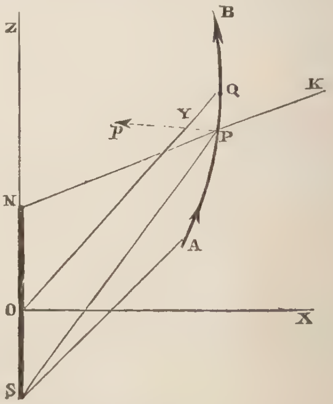

Fig. 40.

---

[1] Reduced to a standard current strength by means of the magnet deflections.

[2] For another verification by Cazin, see Wiedemann, *Galv.*, Bd. ii. § 44.

[3] Maxwell, vol. i., §§ 486 and 491.

[4] We are here supposed to be in *southern* latitudes.

x, y, z; then if l, m, n be the direction cosines of NP, and $NP = D$, we have $Dl = x$, $Dm = y$, $Dn = z - c$; also the direction cosines of Pp, which is perpendicular to NP and PQ, and is the direction of the force exerted by the pole N on P, are

$$\left(n\frac{dy}{ds} - m\frac{dz}{ds}\right) \div \sin QPK, \text{ etc.}$$

Hence by formula (6) the components of the force acting on PQ are

$$\frac{m}{D^2}\left(n\frac{dy}{ds} - m\frac{dz}{ds}\right)i\,ds, \text{ etc.}$$

Hence, if K denote the moment of these forces about OZ, we have from the north pole alone

$$K = mi\int\frac{ds}{D^2}\left\{\left(l\frac{dz}{ds} - n\frac{dx}{ds}\right)x - \left(n\frac{dy}{ds} - m\frac{dz}{ds}\right)y\right\}.$$

If we substitute the values of l, m, n this reduces to

$$K - mi\int ds\frac{d}{ds}\left(\frac{z-c}{D}\right) = mi\int dn.$$

If therefore $\beta_1, \alpha_1, \beta_2, \alpha_2$ denote the angles BNZ, ANZ, BSZ, ASZ, we have, adding the results from both poles,

$$K = mi\,(\cos\beta_1 - \cos\alpha_1 - \cos\beta_2 + \cos\alpha_2). \quad . \quad . \quad (21)$$

It follows from this remarkable formula that the couple K tending to turn a part AB of an electric circuit about the axis of a magnet depends merely on the position of the ends A and B.

In particular, if A coincide with B, *i.e.* if AB form a closed circuit, or if A and B both lie on parts of the axis not included between N and S,[1] the couple will be *nil*, and there will be no rotation.

The application of this formula to cases where there are sliding contacts at A and B not lying on the axis presents no difficulty; we leave it to the reader.

Rotation apparatus.

Several of these rotations may be exhibited by means of the apparatus represented in figure 41. ABC is a horizontal coil of wire terminating at the binding screws a, b. FG is a ring-shaped trough of mercury for the sliding contacts. A wire connects the mercury with the binding screw d. DE is an upright support screwed into a metal base D in connection with the binding screw c, and terminating above in a mercury cup E. When required DE can be replaced by the shorter supports D′E′ and D″E″. HLK is a support for a screw L, which carries an adjustable centre.

1. Poise in the cup E the wire stirrup MN, so that the ends just dip in the mercury trough. Then if a strong current be sent from c to d, MN will rotate (in northern latitudes) in a direction opposite to the hands of a watch.

2. If we fix a vertical magnet $n'''s'''$ to DE by means of a clip at Y, then the rotation will take place with a weaker current in the same direction as before, if the north pole of the magnet be upwards (as shown in figure), but in the opposite direction if the magnet be reversed.

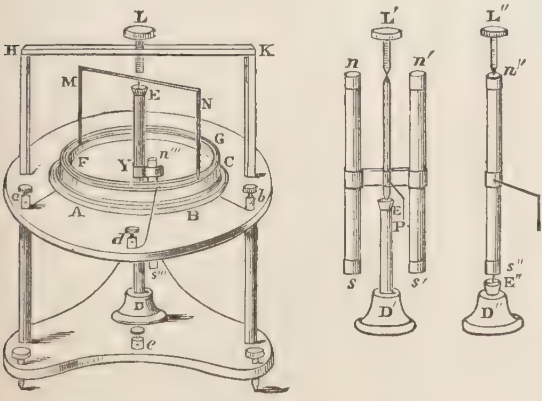

Fig. 41.

3. Reversing the current alone in either of the last two cases causes the direction of rotation to be reversed.

4. The magnet may be removed and a current sent from a to b round ABC in the direction opposite to the hands of a watch. The result is the same as for the magnet with its north pole upwards. If the current in ABC is reversed, the rotation is reversed; and so on.

5. The support D′E′ with the two magnets ns, $n's'$ may be screwed into D instead of DE, the wire P now dipping into the mercury. If the current be sent from c to d, the vertical current in D′E′ will act on s and s', and cause the magnet to rotate in the direction of the hands of a watch. This rotation is reversed if the current go from d to c.

6. We may consider any magnet of finite size as made up of a series of magnets like ns and $n's'$ arranged about an axis. Hence, if we replace D′E′ and the magnets D″E″ by the single magnet supported by means of the pivot L″, there will still be rotation.

Figure 42 represents a very elegant piece of apparatus devised by Faraday, to show the rotation at once of a magnet and of a movable conductor. The rotating pieces are the magnet sn, which is tied to the copper peg at the bottom of G by means of a piece of string, and swims round the vertical current buoyed up by the mercury in G, and the wire DE, which is hinged to D by a thin flexible wire and swims round the pole of the vertical magnet $n's'$.

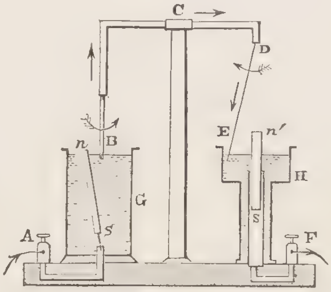

Fig. 42.

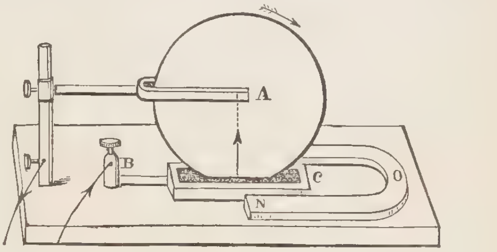

Fig. 43.

Another apparatus invented by Barlow, and known by the name of Barlow's wheel, is represented in figure 43. A current is caused to pass from the mercury trough C along the radius of the disc A through the field of magnetic force due to the horseshoe magnet NO. The result is that the wheel rotates in the direction indicated by the arrow.

Fluid rotations.

Fluid conductors may also be caused to rotate under the action of a magnet. We mentioned in our historical sketch the experiment by which Davy demonstrated this rotation in the case of mercury. A variety of such experiments have been since devised. The following is a simple one. Fill a small cylindrical copper vessel with dilute sulphuric acid and set it upon the north pole of a powerful electro-magnet. If a thick zinc wire be connected by a piece of copper wire to the copper vessel, and then immersed in the acid so as to be in the axis of the vessel, a current is set up in the liquid which flows radially from the zinc to the copper across the lines of force. The liquid therefore rotates in the direction of the hands of a watch.

Action of magnet on electric discharge.

Magnetic Action on the Electric Discharge in Gases.—A large number of very interesting results have been obtained concerning the behavior of the electric discharge in a field of magnetic force. We can only make a brief allusion to the matter here. The key to the phenomena lies in the remark that the electric discharge in vacuum tubes may be regarded as an electric current in a very flexible elastic conductor. It is clear that such a conductor would be an equilibrium if it lay in a line of magnetic force passing through both its fixed ends. Again, if the flexible conductor be constrained to remain on a given surface, it will not be in equilibrium until it has so arranged itself that the resultant electromagnetic force at each point is *perpendicular* to the surface. At each point, therefore, the magnetic force must be tangential to the surface.[1]

---

[1] We might consider what would happen if A or B lay on NS, but the case never arises in practice, for all magnets have a finite thickness (see on this subject Weidemann, Bd. ii. § 119).

A perfectly flexible but inextensible conductor, two points of which are fixed, will take such a form that the electromagnetic force at each point is balanced by the tension. Le Roux fastened a thin platinum wire to two stout copper terminals, and caused it to glow by passing a current through it. When the terminals were placed equatorially between the flat poles of an electro-magnet, the wire bent into the form of a circular arc joining the terminals. When the terminals were placed axially, it assumed a helical form. (See also Spottiswoode and Stokes, *Proc. R. S.*, 1875.)

Rotation of electric discharge.

The behavior of the light emanating from the positive pole may be explained in general as lying between the two cases which we have just discussed. One of the most remarkable of these phenomena is the rotation of the discharge discovered by Walker, and much experimented on by De la Rive. This may be exhibited by means of the apparatus shown in fig. 44, consisting essentially of an exhausted vessel, one of the electrodes in which is ring-shaped; a bar of soft iron, covered with some insulating material, is passed through the ring and fixed to the stand. When this apparatus is placed on the pole of a powerful magnet, the discharge rotates as a wire hinged to the upper electrode would do.

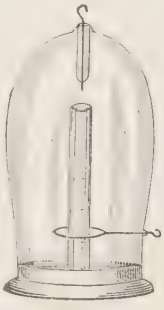

Fig. 44.

Plücker's experiments.

Owing to the distinct character of the negative light, the action of the magnet on it is different from that on the positive light. Plücker found that the general character of the phenomena may be thus described:—The negative light is bounded by magnetic curves that issue from the electrode and cut the walls of the tube.

The two diagrams in fig. 45 will convey an idea of the appearance of the phenomenon. Although much tempted to follow the subject further we must be content to refer the reader to the interesting papers of Plücker[2] and Hittorf.[3] An excellent summary will be found in Wiedemann.

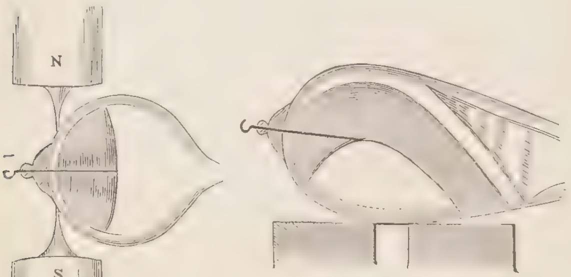

Fig. 45.

Ampère's theory.

Ampère's Method.—Before quitting the subject of electro-magnetism, it will be useful, for the sake of comparison, to give a brief sketch of the method of Ampère, or rather of that modification of the original method now commonly found in Continental books, which was suggested by Ampère himself, in a note to the *Théorie des Phénomènes Électro-dynamiques.* Ampère starts with the idea that the electro-dynamic action of two circuits is the sum of the actions at a distance between every pair of their elements. He supposes, as the simplest and most natural assumption, that the force between two elements is in the line joining them. Besides this assumption, his theory rests on four experiments.[4] The first of these shows that, when a wire is doubled on itself, the electro-dynamic action of any current in it is *nil.* The second experiment shows that this is also true, even if one of the halves of the wire be bent or twisted in any way, so as never to be far removed from the other. The third experiment proves that the action of any closed circuit on an element of another circuit is perpendicular to the element. In the fourth experiment it is shown that the force between two conductors remains the same when all the lines in the system are increased in the same ratio, the currents remaining the same. From the assumption, together with the first experiment, it follows that the force between two elements is proportional to the product of the lengths of the elements, multiplied by the product of the strengths of the currents and by some function of the mutual distance and of the angles which determine their relative position. Hence it may be shown, from the fourth experiment, that the force between the elements must vary inversely as the square of the distance between them. The second experiment shows that we may replace any element of a circuit by the projections of the element on three rectangular axes.

From these results it is found that the force between ds and $d\sigma$ must be

$$-\frac{Aii'dsd\sigma}{D^2}(\cos\varepsilon - k\cos\theta\cos\theta').$$

The constant k is then determined from the result of the third experiment; and it is found that k must be equal to $\frac{3}{2}$. The formula is thus completely determined, with the exception of A, which depends on the unit of current which is chosen. The action of a closed circuit on an element is then calculated, and a vector found, which Ampère calls the "directrix," from which this action can be found in exactly the same way as we derived this same action from the magnetic induction. The theory is then applied to small plane circuits, solenoids, and so on.

As was remarked in the historical sketch, a variety of other elementary laws may be substituted for that of Ampère, all of which lead to the same result for closed circuits.

Generalization of theory.

Maxwell has presented Ampère's theory in a more general form, in which the assumption about the direction of the elementary action is not made. Neglecting couples, he finds for the most general form of the components of the force exerted by $d\sigma$ on ds

$$\left.\begin{array}{l} \mathrm{R} = -\dfrac{1}{\mathrm{D}^2}\left(\dfrac{d\mathrm{D}}{ds}\dfrac{d\mathrm{D}}{d\sigma} - 2\mathrm{D}\dfrac{d^2\mathrm{D}}{dsd\sigma}\right)ii'dsd\sigma + \mathrm{D}\dfrac{d^2\mathrm{Q}'}{dsd\sigma}ii'dsd\sigma \\ \text{in the direction of D,} \\ \text{and} \qquad \mathrm{S} = -\dfrac{d\mathrm{Q}}{d\sigma}ii'dsd\sigma,\ \mathrm{S}' = \dfrac{d\mathrm{Q}}{ds}ii'dsd\sigma \\ \text{in the direction of } ds \text{ and } d\sigma \text{ respectively.} \end{array}\right\} \quad (22)$$

In these expressions Q is a function to be determined only by further assumption. $\mathrm{Q} =$ constant gives Ampère's formula; $\mathrm{Q} = -\frac{1}{2r}$ gives the formula of Grassmann, and so on. We may in fact construct an infinite variety of different elementary formulæ. The reader interested in this subject may consult Wiedemann, Bd. ii. §§ 26, 27, 45–54, etc., and Tait, *Proc. R. S. E.*, 1873.

Action of soft iron.

In our account of the magnetic action of electric currents no mention has been made of the effect of the proximity of soft iron. Under the magnetic action of the electric circuit soft iron is magnetized inductively. The distribution of the lines of force is in general greatly affected thereby. The general feature of the phenomenon is a concentration of the lines upon the iron. By the proper use of this effect electro-magnetic forces of great power may be developed. It is not easy to give a mathematically accurate account of the action, owing to our ignorance of the exact law of magnetic induction in powerfully paramagnetic bodies. The discussion of this subject, however, belongs to **MAGNETISM** (which see).

[4] Details respecting these experiments, and other matter connected with Ampère's theory, may be found in Maxwell, vol. ii. § 502, etc., and in almost any Continental work on experimental physics.

The Induction of Electric Currents.

Faraday's laws of induction.

A brief account has already been given (see Historical Sketch, p. 10) of Faraday's discovery[1] of the induction of electric currents. The results he arrived at may be summed up as follows.

Let there be two linear circuits, ABKE (the primary) and CDG (the secondary), two portions of which, AB and CD, are parallel, and near each other.

I. When a current is started in AB, a transient current flows through CD in the opposite direction to the current in AB; when the current in AB is steady, no current in CD can be detected; when the current in AB is stopped, a transient current flows through CD in the same direction as the current in AB. These currents in CD are said to be induced, and may be called inverse and direct currents respectively, the reference being to the direction of the primary. Both inverse and direct currents last for a very short time, and the quantity of electricity which passes in each of them is the same.

II. If the circuit AB, in which a steady current is flowing, be caused to approach CD, an inverse current is thereby induced in CD; when the circuit AB, under similar circumstances, recedes from CD, a direct current is induced in CD. We have already mentioned that when AB is at rest, and the current in it does not vary, there is no current in CD. AB has been supposed to approach and recede from CD, but the same statement applies when CD approaches and recedes from AB.

III. When a magnet is magnetized or demagnetized in the neighborhood of a circuit, or approaches or recedes from the circuit, the effect is the same as if an equivalent[2] current approached or receded from the circuit. For example, imagine a small circular circuit placed horizontally, and a vertical bar magnet lowered in the axis of the circuit with its north pole pointing down upon the circuit, the magnet may be replaced by a series of coaxial circular currents (see above, p. 67), and the motion will induce a current passing round the circuit against the hands of a watch.

Faraday showed how the direction of the induced current can be predicted when the variation of the magnetic field or the motion of the conductor in it is known, and he gave in his own manner, indications how the magnitude of the current could be inferred.

Maxwell's statement.

Maxwell has thrown the law of Faraday into the following form:—"The total electro-motive force acting round a circuit at any instant is measured by the rate of decrease of the number of lines of magnetic force which pass through it."

Or, integrating with respect to the time:—"The time integral of the total electro-motive force acting round any circuit, together with the number of lines of magnetic force which pass through the circuit, is a constant quantity."

For "number of lines of force" may of course be substituted the equivalent expressions, "induction through the circuit," or "surface integral of magnetic induction," taken over any surface bounded by the circuit.

Some care must be taken in determining the positive direction round the circuit. The following is a correct process:—Assume one direction (D, fig. 46) *through* the circuit as positive, then the positive direction *round* (R) is determined by the right-handed screw relation; if the number of lines of force reckoned positive in direction D is decreasing, then the electro-motive force is in direction R; if that number is increasing, the electro-motive force is in the opposite direction.

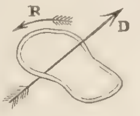

Fig. 46.

This will be clearer if we consider the following simple example. Let ABCD (fig. 47) be a horizontal rectangular circuit (AB next the reader). In a northern latitude, the vertical component Z of the earth's magnetic force is downwards; if, therefore, the positive direction through the circuit be taken downwards, the positive direction round is ADCB, and the number of lines of force through it is Z.AB.BC. If BC slide on DC and AB parallel to itself through a small distance BB′ in time τ, Z.AB.BC *increases* by Z.CB.BB′; hence the electro-motive force is Z.BC.BB′ ÷ τ, and acts in the direction ABCD. If v be the velocity of BC, we may write for the electro-motive force Z.BC.v. That is, the electro-motive force at any instant is proportional to the velocity.

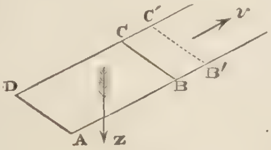

Fig. 47.

The law of Faraday leads to a complete determination of the induced current in all cases. We may regard it as resting on the experiments of Faraday, and of those who followed out his results.

Theory of Helmholtz and Thomson.

Another view of the matter of great importance was enunciated independently and about the same time by Helmholtz[3] and Sir William Thomson.[4]

Let a circuit carrying a current[5] i move in an invariable magnetic field, so that the number of lines of magnetic force passing through it is increased by dN, then the work[6] done by the electro-magnetic forces on the circuit is by Ampère's theory idN; also, if R be the resistance of the circuit, Ri^2dt is the heat generated in time dt. Now if E be the electro-motive force of the battery which maintains the current i, the whole energy supplied is Eidt; hence we must have

$$idN + Ri^2dt = Eidt$$

$$\text{and } i = \left(E - \frac{dN}{dt}\right)\frac{1}{R} \quad . \quad . \quad . \quad . \quad . \qquad (23)$$

Hence there is an electro-motive force $-\frac{dN}{dt}$ in the moving circuit. Now $\frac{dN}{dt}$ is the rate of increase of the number of lines of force passing through the circuit.

We have therefore deduced the law stated above from Ampère's theory and the principle of the conservation of energy; at least we have done so for the case of induction by permanent magnets, and the same reasoning will also apply to the case where the alteration of the magnetic field, owing to the induced current in the primary circuit, is so small that it may be neglected.

Electro-magnetic unit of electro-motive force.

We have now the means of stating in a convenient form the electro-magnetic unit of electro-motive force. It is the electro-motive force of induction in a circuit the number of lines of magnetic force through which is increasing at the rate of one per second.

In the case where the field is due to a current i', we have by formulæ (4) and (14) of last division

$$N = i'M, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (24)$$

where M now stands for $\iint \frac{\cos \epsilon}{D} ds d\sigma$ extended all over the two circuits. M, which depends merely on the configuration and relative position of the two circuits, is called the coefficient of mutual induction.

Electro-kinetic energy. Theory of Thomson.

An application of the principle of the conservation of energy of great importance was made by Sir William Thomson to the case of two electric circuits of any form, in which the currents are kept constant.

Let two such circuits, the currents in which are ii', be displaced so that the coefficient of mutual induction M increases by dM. Let us suppose that the currents i and i' are maintained by two constant batteries of electro-motive forces E and E′, and that the motion takes place *so slowly* that the currents may be regarded as constant throughout. If R and R′ be the resistances of the circuits, Hdt the mechanical equivalent of the whole heat generated, and Kdt the whole expenditure of chemical energy in the batteries in time dt,

$$H = Ri^2 + R'i'^2, \text{ and } K = Ei + E'i',$$
$$K - H = i(E - Ri) + i(E - R'i').$$

Now, applying (23),

$$Ri = E - i'\frac{dM}{dt}, \text{ and } R'i' = E' - i\frac{dM}{dt};$$

whence $$K - H = 2ii'\frac{dM}{dt},$$

or, as we may write it,

$$(K - H)dt = 2ii'dM. \quad . \quad . \quad . \quad . \qquad (25)$$

Now $ii'd$M is the work done by the electro-magnetic forces during the displacement which we may suppose spent in lifting a weight.

---

[1] *Exp. Res.*, ser. i., ii., (ix.), xxviii., xxix., 1831-32, 1851. The general statement in the text is given for the reader's convenience, and is not meant to be historical.

[2] Equivalent in the sense of producing the same magnetic field.

[3] *Ueber die Erhaltung der Kraft*, 1847.

[4] *Rep. Brit. Ass.*, 1848, and *Phil. Mag.*, 1851.

[5] All the quantities are supposed to be measured in electro-magnetic absolute units.

[6] We may suppose this work spent in raising a weight, etc.

Hence, when two electric currents are allowed slowly to approach each other, being kept constant and doing work the while, over and above the work which is spent in generating heat in the conductors, an amount of energy is drawn from the batteries equivalent to twice the work done by the electro-magnetic forces.

There remains therefore an amount of work as yet unaccounted for. What becomes of it? The answer is, that the energy, or, as Sir W. Thomson calls it, the "mechanical value," of the current is increased. But how increased? When a material system (and we may consider the two circuits, the batteries, the lifted weight, etc., as such) is left to itself, it moves so that its *potential* energy *decreases.* In this case, therefore, there must have been an increase of *kinetic* energy somewhere. This energy may be called the electro-kinetic energy of the system; according to Maxwell's theory, this kinetic energy has its seat in the medium surrounding the wire. The energy thus stored up is accounted for in the increased development of heat, etc., when the two currents are broken in succession.

Case of two circuits.

Returning now to our general law of induction, let us write down in the most general form the equations which determine the course of the currents in two circuits (A, B), in which the form and relative positions of the circuits, as well as the current strengths, are variable. The number of lines of force which pass through a circuit depends partly on neighboring circuits, partly on the circuit itself. Retaining the notation used above, we may, in the case of two circuits, write the first part Mi', and the second part Li, where L is a double integral of the same form as M, only both elements ds and $d\sigma$ now belong to the same circuit. We have, therefore, for the whole number of lines of force passing through the circuit A, $Mi'+Li$. Similarly we have for B, $Mi+Ni'$. We have therefore by our general law,

$$\left.\begin{aligned} E-\frac{d}{dt}(Mi'+Li)&=Ri \\ E'-\frac{d}{dt}(Mi+Ni')&=R'i' \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (26)$$

These are the general equations for the induction of two circuits. The electro-motive force of induction in A can be divided into two parts: one of these, viz., $\frac{d}{dt}(Mi')$ is due to the circuit B, the other $\frac{d}{dt}(Li)$ is due to the circuit A itself, and is called the electro-motive force of self-induction. L is called the coefficient of self-induction for A. Similarly $\frac{d}{dt}(Ni')$ is the electro-motive force, and N the coefficient force of self-induction for B.

If we have only one circuit then $M=0$, and the equation for the course of the current is

$$E-\frac{d}{dt}(Li)=Ri;$$

here there is only self-induction.

Theory of Neumann. Law of Lenz.

F. E. Neumann, to whom belongs the honor of first stating, with mathematical accuracy the laws of induction, adopted a foundation for his theory very different from the one chosen above. His method was based on the law of Lenz,[1] enunciated very soon after the great discovery of Faraday, which lays down that, in all cases of induction by the motion of magnets or currents, the induced current has a direction such that its electro-magnetic action on the inducing system tends to oppose the motion producing it.

Besides its historical importance, this law affords a very convenient guide in many practical applications of the theory of induction. The reader will find no difficulty in verifying it on the elementary cases given at the beginning of this division. It can be deduced at once from our general law. Consider any circuit in which a current i is flowing, and let the direction of the current be the positive direction round the circuit. Suppose the circuit to move so that the number of lines of force passing through it increases, this is the way the circuit would tend to move under the electro-magnetic forces when traversed by a current i; but the electro-motive force of induction is in the negative direction round the circuit by the general law, and would therefore produce a current opposite in direction to i. The electro-magnetic action on this current would be opposite to that on i; that is, would tend to hinder the displacement. It is a curious fact that a law exactly like this had been announced shortly before Lenz by Ritchie, only with the direction of the action *reversed* in every case.

The results of Neumann are identical with those given above. The double integral M, which is here called the coefficient of mutual induction of two circuits, Neumann calls the mutual *potential* of the two circuits, and what has been called above the coefficient of self-induction of a circuit he calls the *potential of the circuit on itself.* Accounts of his theory will be found in Wiedemann's *Galvanismus,* and in most Continental works on electricity.

Experimental Verification of the Laws of Mutual Induction.—It will be observed that, in the law of induction for linear circuits, no statement is made respecting the material or thickness of the circuit in which the electro-motive force of induction acts, or of the non-conducting medium across which induction takes place.

Experiments by Faraday.

Faraday showed that the material of the circuit has no effect.[2] He found, for instance, that when two wires of different metals were joined and twisted up together, as in fig. 48, so as to be insulated from each other, no induced current could be obtained by passing the arrangement between the poles of a powerful magnet. The same result was obtained when one of the branches of the circuit was an electrolyte. Lenz[3] connected two spirals of wire in circuit with each other, and placed first one then the other, on the soft iron keeper of a horse-shoe magnet; so long as the number of turns on each spiral was the same, the induced current was the same, no matter what the material or thickness of the wire in each spiral. Since in this case the whole resistance of the circuit was always the same, the electro-motive force of induction must have been the same.

Fig. 48.

We conclude, therefore, that the electro-motive force[4] of induction is independent of the material, and also of the thickness of the wire, so long as the latter is so small that we may consider the wire as a linear circuit.

Lenz.

Lenz made quantitative determinations of the induced current by means of the above arrangement.

The soft iron keeper, with a coil of n windings, was rapidly detached from the magnet, and the first swing α of a galvanometer in circuit with the coil was measured. The quantity of electricity which passes in the induced current is measured by $\sin\frac{1}{2}\alpha$, provided the whole duration of the current is small compared with the time of oscillation of the galvanometer needle (see art. GALVANOMETER). Again, when the keeper is attached to the magnet, very nearly all the lines of magnetic induction[5] pass through the keeper; hence the number of lines of induction which pass through the coil is very nearly proportional to the number of windings, and therefore, if the resistance of the circuit be kept the same, the whole amount of electricity which passes will be proportional to n. In the actual experiment the wire was wound and unwound from the keeper, so that the whole resistance did remain the same. The following is a set of Lenz's results:[6]

No. of windings....	2	4	8	12	16	20
$\sin\frac{1}{2}a$......	0·0491	0·1045	0·2156	0·3319	0·4470	0·5594
$\sin\frac{1}{2}a \div n$......	0·0245	0·0261	0·0270	0·0276	0·0279	0·0280

The value of $\sin\frac{1}{2}\alpha \div n$ is very nearly constant. It increases a little as the number of windings increases, as ought to be the case, for, although most of the lines of induction pass through the keeper, yet all do not, and a few more are included when the number of turns is increased.

Effect of medium.

Faraday made special investigations in search of the effect of the medium across which induction is exerted. He found[7] that no effect on the integral current was produced by inserting shellac, sulphur, copper, etc., between the primary and secondary coils. The insertion of iron or any strongly magnetic body, of course, produces an effect, because the distribution of the lines of magnetic force is thereby altered, and therefore, by our general law, the electro-motive force of induction will be correspondingly affected. We conclude, therefore, that the electro-motive force of induction is independent of the medium across which it is exerted.[1]

[2] *Exp. Res.*, 193, etc., 1832; also 3143, etc., 1851.

[3] *Pogg. Ann.*, 1835.

[4] Of course the same is not true of the current of induction, which depends on the resistance of the circuit.

[5] In Maxwell's sense; we might say "lines of magnetic force" in Faraday's sense; see art. MAGNETISM.

[6] Wiedemann, Bd. ii. § 706.

[7] *Exp. Res.*, 1709, etc., 1838.

It must be remarked, however, that in the case of conducting media, the statement is subject to a certain limitation, the nature of which follows from the law of induction itself. For there will be induced currents in the intervening medium if it be a conductor, and these currents will disturb the lines of force while they continue to flow. These currents are *transient*, however, so that their integral effect on the number of lines of force passing through the secondary is zero. It is obvious, therefore, that, if we replace "electro-motive force" by "time integral of electromotive force extended over the whole time that the induction currents last," the statement will still be true. The only effect, therefore, of interposed conducting media is on the *time* which the induced currents take to rise and fall.

Weber's experiments.

Weber[2] applied his electro-dynamometer to test the laws of induction.

The suspended coil was caused to oscillate when there was no current either in it or in the fixed coil, and the logarithmic decrement[3] of its oscillations carefully determined. This decrement, due to the friction of the air, etc., was found to be constant for different lengths of the arc of oscillation. The terminals of the suspended coil were next connected so that it formed a closed circuit, and a constant current was sent through the fixed coil. Induction currents were now generated in the suspended coil, whose electro-dynamic action constantly opposed its motion. It was found that the logarithmic decrement was still constant, but greater than before. Weber therefore concluded that the induced current at each instant was proportional to the velocity of the coil. Since the resistance does not vary, this is in accordance with the general law.

Weber further showed that the induced current is the same whether it is produced by a current in the fixed coil or by a magnet, which exercises the same electro-magnetic action as that current on the suspended coil, when the latter is traversed by a current of unit strength.

The electro-dynamometer may also be used to demonstrate the equality of the whole amounts of electricity which pass in the direct and inverse currents. If the induced currents from a secondary coil whose primary is being "made and broken" be passed through both coils of the instrument, there will be a deflection, since the action depends on the square of the current; but if the induced current be sent through the suspended coil alone, and a constant current be sent through the fixed coil, there will be no deflection, which shows that the quantities of electricity passing in the alternate currents of the secondary coil are equal and of opposite sign.

Felici.

Felici (1852 and 1859) made an extended series of experiments on the laws of induction. He used null methods, and his experiments bear a resemblance in some respects to the electro-dynamical experiments of Ampère. Maxwell[4] has given a summary of Felici's results.

It is found, for instance, that the electro-motive force of induction of a circuit A on another B is independent of the material or section of the conductors, that it is proportional to the current in A and to the number of windings in B. The induction of A on B is the same as that of B on A, when the inducing current *i* is the same in both cases. Any portion of A or B may be replaced by a zig-zag portion, which nowhere deviates far from it. In pairs of circuits geometrically similar, the electro-motive force of induction is proportional to the linear dimensions, and so on.

If B be so situated with respect to A that starting or stopping a current in A produces no induced current in B, B is said to be conjugate to A. There are an infinite number of such conjugate positions of B; and Felici shows that, if B be moved from one these P_1 into another P_2 very quickly, no effect is produced on the galvanometer. If B be moved from P_1 to any position P (not a conjugate position), the effect on the galvanometer is the same as if the current *i* were suddenly started in A, B being in the position P.

All these results are direct consequences of our general law, and indeed might be used as a foundation for it.[5]

Faraday's exploring conductor.

In his later researches on electro-magnetic induction (series xxvii. and xxix.), Faraday develops in considerable detail his ideas on the connection between the lines of magnetic force and the induced current, and gives increased precision to the experimental methods that flow therefrom. He points out the great value of methods, such as the use of iron filings, for exhibiting in a visible form the course of the lines of magnetic force. He also insists on the great use of a small moving circuit, which can be used to explore the magnetic field under circumstances which render the application of other methods impossible.

The direction of a line of force may be determined in various ways by means of the moving conductor. Maxwell[6] gives four such ways:—(1) if a conductor be moved along a line of force parallel to itself, it will experience no electro-motive force; (2) if a conductor carrying a current be free to move along a line of force, it will show no tendency to do so; (3) if a linear conductor coincide with a line of force and be moved parallel to itself in any direction, it will experience no electro-motive force in the direction of its length; (4) if a linear conductor carrying an electric current coincide in direction with a line of magnetic induction, it will not experience any mechanical force.

Unipolar induction.

In these researches Faraday treats at considerable length a case of the induction of electric currents, to which Continental writers have given the somewhat mysterious name of "unipolar induction." It belongs to a class of cases on which they have rightly dwelt as being in a sense the reverse of the electro-magnetic rotations. The following theory of the phenomenon will make this clearer:—

Referring back to figure 40, let AB be part of a conducting circuit arranged as there described, and let it be caused to move in the direction P*p*. Then if E be the electro-motive force in the circuit in the direction AB, N the number of lines of force passing through the circuit, ϕ the angle through which AB moves (from X to Y) about OZ, we have, by our general law,

$$\mathrm{E} = -\frac{d\mathrm{N}}{dt} = -\frac{d\mathrm{N}}{d\phi}\frac{d\phi}{dt}.$$

Now, by Ampère's theory, $\mathrm{K} = \frac{i d\mathrm{N}}{d\phi}$, hence (p. 68)

$$\begin{aligned}\mathrm{E} &= -\frac{\mathrm{K}}{i}\frac{d\phi}{dt} \\ &= -m(\cos\beta_1 - \cos\alpha_1 - \cos\beta_2 + \cos\alpha_2)\frac{d\phi}{dt}. \qquad (27)\end{aligned}$$

Hence, if the conductor AB be caused to move with given angular velocity about the magnet SN, in that direction which it would take under the action of the magnet if it carried a current *i*, then there will be an electro-motive force of induction along the circuit of which AB forms part, whose direction is opposite to that of *i*, and whose magnitude is found by dividing the couple acting on AB (when traversed by *i*) by *i*, and multiplying it by the given angular velocity. This result is a beautiful instance of the law of Lenz.

A great variety of experimental arrangements may be imagined to realize the case thus described. Every apparatus devised to produce an electro-magnet rotation may be used to illustrate it.

The following case may be taken as typical. SN (fig. 49) is a bar magnet whose action may be represented by two poles, N and S. At the middle point of its axis is fixed a disc BA, against which presses the terminal of a wire CA in metallic connection with the axis through the pivot at S. If CA be caused to rotate in the direction of the arrow *p*, the disc standing still, there will be an induced current in CABC in the direction of the arrow *q*. If CA and the disc revolve together, there will be no current. If CA stand still, and the disc rotate in the direction of the arrow, there will be a current in the opposite direction; for this is clearly the same as if the disc stood still, and CA rotated in the opposite direction.[7] The electro-motive force in each case is independent of the form of CA, and is given by $2m(1-\cos\alpha)\omega$, where m is the strength of the pole N, α the angle ANB, and ω the angular velocity.

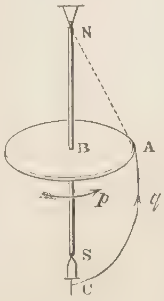

Fig. 49.

---

[1] Other investigators have sought for such effects, and some have affirmed their existence; but there is no body of concurrent testimony on the point.

[5] See Maxwell, *l.c.*

[6] Vol. ii. § 597.

[7] If the reader wish for a proximate rule for the direction of the electro-motive force of induction, the following will serve. Stand with the body in the line of magnetic force with the head pointing in the positive direction, look in the direction in which the part of the circuit on which the feet are is moving; the E. M. F. along the circuit is towards the right hand.

It is well to remind the reader that the lines of force are closed curves, every one of which passes up the axis of the magnet from S to N, and back through the outside medium to S. If this be forgotten, and an attempt be made to determine the electro-motive force of induction by considering the motion of the *disc*, an error will easily be made. If we take the simpler course above, and consider the motion of the *conductor*, there is then no danger of mistake.

Coils with iron core.

In most of the experiments we have hitherto been describing, the object has been to obtain indications of the direction of the currents of induction, or to measure the electro-motive force of induction under definite circumstances; if, however, we desire to exhibit the effects of induction in a striking manner, in order to convey belief to the spectator, or to serve some practical purpose, recourse is had to a different kind of apparatus. We may wind our primary and secondary coils on bobbins, and insert the former within the latter, so as to get the greatest possible number of turns of wire into proximity. The number of turns on the primary is usually made small, in order that the current in it may not be weakened by a large resistance, and that its coefficient of self-induction (see below) may be small. Mention has already been made of the effect of soft iron in increasing the number of lines of force that pass through a circuit. It is easy to see that it will produce a corresponding effect in strengthening induction. The precise amount of it is very hard to calculate, owing to the irregularities in the magnetization and demagnetization that arise from residual magnetism. The question belongs, however, to magnetism. The effect can be demonstrated practically by observing the alteration in the inductive action produced by inserting a bundle of iron wires[1] into our primary coil.

Physiological effects.

The physiological effects of induced currents are very striking; indeed, the nerve and muscle preparation of the physiologist affords a very delicate method for detecting them. If the human body form part of the circuit of the secondary coil of such an induction apparatus as we have just indicated, and the primary current be stopped and started in rapid succession, say by stripping one terminal of the circuit on a toothed wheel attached to the other, a sensation is experienced which, with a moderately powerful apparatus furnished with a core, is so painful and peculiar that the patient is not likely to forget either it or its cause. The tetanic muscular contractions produced in this way have formed the subject of much physiological investigation, of which an account will be found in the proper place (see article PHYSIOLOGY).

The flat spirals of Henry, formed of flat bands of copper insulated from each other with silk ribbon, are also very convenient for demonstrating the existence of induced currents.

The most powerful inductive apparatus for furnishing large quantities of electricity are the various magneto-electric machines which have now been brought to great perfection (see Historical Sketch).

By means of these and similar appliances, all the effects of the electric current and the electric discharge may be shown in the greatest perfection.

Induction by statical discharge.

Induction by Discharge of Statical Electricity.—The phenomena of induction can be exhibited with the transient current of electricity in the discharge of a Leyden jar or other accumulator of statical electricity. There is a difficulty in exhibiting the effect, owing to the great differences of potential between different parts of the circuit, which render the application of a coil of silk-covered wire useless. A common way of getting over the difficulty consists in cutting two spiral grooves in two flat ebonite discs. Wires are embedded in these, and they are then put together with a thin plate of glass between, so that the spirals are opposite each other. When a jar is discharged through one spiral, an induction current passes in the other, and may be indicated by a galvanometer, or, better still, by a frog preparation. The induced current is, however, in general a complicated phenomenon, owing to the oscillatory nature of the discharge (see above, p. 61).

It would lead us too far to go into these and kindred subjects: the reader who desires to pursue the matter will find excellent accounts in Mascart, t. ii. §§ 611–825, and Riess, Bd. ii. §§ 780–906. Particularly interesting are the researches of Verdet, an account of which will be found in his works, along with many indications of what others have done in the same field.

Induced currents of higher orders.

Induced Currents of Higher Orders.—Induced currents may in their turn induce other currents, and these again others, and so on.[2] This can be brought about by forming part of the secondary circuit of one inductive apparatus into the primary of the next, and so on. As may be supposed, the successive induced currents diminish very rapidly in strength, and require special means for their detection. But the phenomenon also goes on increasing in complicacy. Suppose we start the current in the first primary, there is a single inverse current of the "first order" which rises and then falls; there will, therefore, be two currents of the "second order"—first a direct, then an inverse; each of these rising and falling causes two currents of the third order, and so on in geometric progression. These currents have been detected in certain cases by means of their physiological action and their magnetizing powers. The latter effects present some points of interest in connection with magnetism, but we cannot spare space for the matter here.

Jenkin's observations.

Self-Induction.—The existence of self-induction has been deduced as a theoretical consequence of the general law of induction. It was not so discovered, however. It was first arrived at by Faraday[3] from experimental considerations. The observation from which he started was the following fact communicated to him by Mr. Jenkin, who had shortly before discovered it:—Although it is impossible with a short circuit of wire and a single battery cell to obtain a shock by making and breaking contact, yet a very powerful shock is obtained if the coil of an electro-magnet be included in the circuit. This may be shown thus:—Let ZC (fig. 50) be a battery of a single cell, CABDEF a circuit with a cross branch BF, in which at G the human body, etc., may be inserted. Contacts can be made and broken at A, very rapidly if need be, by means of a toothed wheel. When BDEF consists of a short single wire, nothing particular is felt at G, but when the coil of an electro-magnet is inserted in DE, the patient at G experiences a series of powerful shocks comparable to that obtained from the secondary coil of an inductive apparatus in the manner already described.

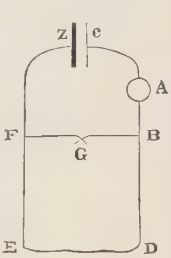

Fig. 50.

Faraday's explanation.

If the cross circuit be done away with, a powerful spark is obtained at A on breaking contact, but none on making. This spark is particularly bright if a mercury contact be used, owing to the combustion of the mercury. If, however, the electro-magnet be removed from DE, and a short wire substituted, the spark becomes quite insignificant, although the whole circuit may be now very hot, owing to the increased current. Faraday found that the same effect, only smaller, was produced when a simple helix without a core was substituted for the electro-magnet; and a similar effect, only still smaller, was obtained when a very long straight wire was used. Faraday soon recognized that these effects are consequences of the laws at which he had arrived in his first series of researches on induction. When the current is rising in a circuit, the number of lines of magnetic force passing through it is on the increase, hence an electro-motive force is generated which opposes that of the battery, and causes the current to rise slowly; again, when the current begins to decrease the number of lines of force begins to decrease, and an electro-motive force of induction is called forth which tends to prolong the current. We have, therefore, a weakening of the electro-motive force at starting and an exaltation at stopping, which accounts for the absence of the spark or shock at make, and the presence of one or other at break. Such inductive effects are obviously heightened when the current is wound into a spiral form; if, however, the spiral were wound double, and the current sent through the two wires in opposite directions, the inductive effects would annul each other, and, in fact, with this arrangement the spark and shock are extremely small.

---

[1] The iron is broken up into wires to prevent the formation of induced currents in the body of the metal. These currents retard the rise of the induced currents.

[2] Some physicists have called these currents induced currents of the second and third orders, etc.

[3] *Exp. Res.*, 1048, etc., 1834.

His experiments.

Faraday demonstrated the existence of these electro-motive forces by means of the currents which they produce in derived circuits,[1] when the battery contact is broken or made.

He used the arrangement given in figure 50. A galvanometer was inserted at G, and the needle stopped by pins properly placed from deviating as urged by the branch of the battery current from B to F, but left free to move in the opposite direction. It was found that the needle deviated sharply when contact was broken at A, in a direction indicating a current from F to B. Again the contact was made, and the needle stopped at the deviation due to the current from B to F, so that it could not return to zero. The contact was then broken and made again, and it was found that at the make the needle tended to go beyond the position due to the steady current in BF. Faraday also arranged a platinum wire at G, so that it did not glow under the steady current in BF, but immediately ignited when the contact at A was broken. Chemical action was produced in a similar manner. In fact we may, by taking advantage of the self-induction, cause a single cell to produce decomposition of water and evolution of gas, which it could not do alone consistently with the conservation of energy. This may be managed[2] by inserting at A (fig. 50), instead of the contact breaker, the coil of an electro-magnet, and placing the decomposing cell in DE. Let contact be made and broken at G (say by an automatic break); when the contact is made the current flows through the coil and through BF, when it is broken the electro-motive force of induction added to that of the battery enables the current to pass through the cell and liberate the ions. At the make there is no such effect; there results therefore continued chemical decomposition.

Edlund's measurements of extra current.

Edlund[3] investigated the integral electro-motive forces of self-induction at the opening and closing of a circuit, and showed that they are equal. His experimental arrangement is very ingenious:—

G (fig. 51) is a differential galvanometer, A a coil whose self-induction is to be examined, C a wire wound in a zig-zag[4] so as to have no self-induction. The battery E is connected at B and D with the circuit composed of G, A, and C, so that the currents in B*cd*CD and B*ba*AD pass round the coils of G in opposite directions. The resistance C is so arranged that there is no deflection of the needle in G. If now the current be stopped by breaking the circuit EB at K, the electro-motive force due to the self-induction of A causes an extra current to flow round the circuit A*ab*B*cd*CD, traversing the coils of G in the same direction. We therefore get a deflection D_1. In a similar manner if we make contact at K we get another deflection D_2, due to the starting of the current in A. There is no difficulty in showing that, if E_1, E_2 be the time integrals of the electro-motive force in the two cases, then

$$\frac{E_1}{E} = \frac{D_1}{D_2}$$

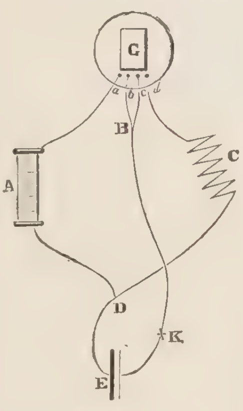

Fig. 51.

One of the difficulties encountered in such experiments is the increase of the electro-motive force of the battery E when it is left open for a time; this causes the extra current at make to be greater than that at break. Rijke, who made experiments similar to those of Edlund, avoids this difficulty by circuiting the battery, when BK is broken, through a resistance equal to the effective resistance from E to K. Further details concerning the method and results of these experiments may be found in Wiedemann, Bd. ii. § 744, etc.

Maxwell's method.

A very convenient method for exhibiting and measuring the extra current is obtained by using a Wheatstone's bridge instead of a differential galvanometer. Let the bridge be balanced as usual, so that when the battery circuit is made, and the galvanometer circuit made afterwards, there is no deflection. If one of the resistances be wound so as to have a large coefficient of self-induction, and the galvanometer circuit be completed before the battery is thrown on, then, owing to the self-induction, the galvanometer needle will be suddenly deflected.

Let AC, CD, DB, BA be four conductors of resistance S, Q, P, R, arranged as a Wheatstone's bridge (see fig. 22), with a battery between A and D, and a galvanometer G between B and C. Let L be the coefficient of self-induction of the coil S. Then, A, C, etc., denoting the potentials at A, C, etc., x and y the currents in AC and AB, and z the current in G, we have

$$A - C = Sy + L\frac{dy}{dt},\ A - B = Rx,\ C - D = Q(y + z),$$

etc. Eliminating, as in Maxwell, vol. i. p 399, or above, p. 40, we get

$$z = \frac{PS - QR + PL\frac{d}{dt}}{D'}E, \quad . \ . \ . \ . \ . \quad (28)$$

where $\frac{d}{dt}$ is a separated symbol, and D' is the determinant of the system of resistances with $S + \frac{d}{dt}$ written for S. We may therefore write

$$D' = D + HL\frac{d}{dt},$$

D being the ordinary determinant, and H a function of PQR, etc., which we need not determine. Equation (28) may therefore be written

$$Dz + HL\frac{dz}{dt} = PL\frac{dE}{dt}, \quad . \ . \ . \ . \ . \quad (29)$$

provided the bridge be balanced, *i.e.* if PS — QR be zero. Suppose now the galvanometer circuit is closed, and then the battery circuit closed; then, integrating equation (29), from the instant before the battery is thrown in up to a time τ when all the currents have become steady and no further current flows through the galvanometer, we get

$$D\int_0^\tau z\,dt = PLE,$$

$$\text{or} \quad z_1 = \frac{PLE}{D}, \quad . \ . \ . \ . \ . \ . \quad (30)$$

where z_1 denotes $\int_0^\tau z\,dt$, *i.e.* the whole amount of electricity that flows through the galvanometer owing to the induced current. If now we derange the balance in the bridge by increasing S by a small quantity x, and decreasing Q by as much, we get a steady current through the galvanometer given by

$$z = \frac{(P + R)xE}{D}.$$

Hence

$$\frac{z_1}{z} = \frac{PL}{(P + R)x}. \quad . \ . \ . \ . \ . \quad (31)$$

Now, if β be the first swing of the galvanometer needle, owing to the induction current, α the deflection under the steady current, and T the time of oscillation of the needle under the earth's force alone (T is supposed to be so large that the duration of the induced current is very small compared with it); then it may be shown that

$$\frac{z_1}{z} = \frac{T\sin\frac{1}{2}\beta}{\pi\tan\alpha}. \quad . \ . \ . \ . \ . \ . \ . \quad (32)$$[5]

Hence

$$L = \frac{(P + R)xT\sin\frac{1}{2}\beta}{P\pi\tan\alpha}. \quad . \ . \ . \ . \ . \quad (33)$$

We thus get L in terms of quantities which can be easily measured. This method of finding L is due to Maxwell.

Calculations of Helmholtz.

The application of the equations (26) to determine the march of the current in certain simple cases leads to results of great interest.

Suppose that an electro-motive force E begins to act in a circuit of resistance R and coefficient of self-induction L. The equation for the current strength i at any time t after it has begun to act, is

$$L\frac{di}{dt} + Ri = E. \quad . \ . \ . \ . \ . \ . \quad (34)$$

$$\text{The integral of this is } i = \frac{E}{R}\left(1 - e^{-\frac{R}{L}t}\right), \quad . \ . \ . \ . \quad (35)$$

---

[1] These currents are sometimes called extra currents, and the name is applied even when there is no alternative circuit. The extra currents are then the defect or excess of the currents at the make and break, considered with reference to the steady current.

[2] De la Rive, Wiedemann, Bd. ii. § 740.

[3] *Pogg. Ann.*, 1849.

[4] The best arrangement would be to use insulated wire and double it on itself.

[5] Certain corrections would in general be necessary in practice, but we need not discuss them here.

the constant of integration being determined by the condition $i=\frac{E}{R}$(= steady current) when $t=\infty$.

Hence the current starts with the value zero, and increases continuously till it reaches the steady value $\frac{E}{R}$.

The part $-\frac{E}{R}e^{-\frac{R}{L}t}$ is due to self-induction, and is called the extra current. The whole amount of electricity passing in this part of the current is

$$-\frac{EL}{R^2}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (36)$$

Time constant of a coil.

The quantity $\frac{L}{R}$ is of the same dimension as t, and is called the time constant of the coil. According as the time constant is greater or less, the longer or shorter time will the current take to rise to a given fraction of its steady value. If we desire therefore to prolong the induction and to increase it as well, we must make L large and R small, two conditions which in the extremes are inconsistent. Calculations of the form of coil for maximum inductive effects might be made, but this is not the place to enter on them.

Next, let the electro-motive force E suddenly cease to act, the resistance of the circuit being unchanged. This may be realized experimentally within certain limits by throwing the battery out of the circuit, and at the same time substituting for it a wire of equal resistance. It is easy to show as above that the extra current at a time t after E ceases to act is

$$+\frac{E}{R}e^{-\frac{R}{L}t},$$

and the whole amount of electricity which passes is $+\frac{EL}{R^2}$.

Experiments of Helmholtz.

Helmholtz,[1] who was the first to treat this subject both experimentally and mathematically, operated as follows:—

(1) The battery was thrown into the circuit, and after a time t the circuit was broken.

(2) The battery was thrown in, and after a time t replaced by a circuit of equal resistance.

These changes were effected by means of a system of levers, which it is not necessary to describe here. An account of the apparatus will be found in the paper quoted.

The amount of electricity which passes through the circuit is measured by a galvanometer whose time of oscillation is long compared with t. In the first case the amount is

$$A=\frac{Et}{R}-\frac{EL}{R}\left(1-e^{-\frac{R}{L}t}\right);$$

in the second

$$B=\frac{E}{R}t,$$

because here the two extra currents just counterbalance each other.

The observed value of B in each case enables us to calculate t. E and R being found by separate observations, one observed value of A enables us to calculate L. Using these values of E, R, and L, a series of values of t, and hence A, can be calculated from the observed values of B, and the result compared with the observed value of A. The agreement between theory and experiment was sufficiently close to justify the application of the principles from which the above formulæ were deduced. Among these principles may be mentioned the validity of Ohm's law for transient currents.

The reader will find in the original paper details concerning the above and other similar results arrived at by Helmholtz.

Two fixed circuits.

The case of two circuits of invariable form and position is of great interest, from the light it throws on the action of the induction coil. We shall suppose that we have no soft iron core, and that the break in the primary is instantaneous. The latter condition is very far from being realized in practice, even with the best arrangements, so that our case is an ideal one.

Let i and j be the current strengths in primary and secondary, R and S the resistances, L, M, N the coefficients of induction, E the electro-motive force in the primary. The equations are

$$L\frac{di}{dt}+M\frac{dj}{dt}+Ri=E, \quad . \quad . \quad . \quad . \quad . \quad (37)$$

$$M\frac{di}{dt}+N\frac{dj}{dt}+Sj=0. \quad . \quad . \quad . \quad . \quad . \quad (38)$$

It is easy, in the first place, to show that the whole amounts of electricity which traverse the secondary at make and break of the primary are equal but of opposite signs. In fact, if we integrate (38) from the instant before make to a time when the induction currents both in primary and secondary have subsided, we get

$$\int j dt=-\frac{M}{S}I=-\frac{ME}{SR}, \quad . \quad . \quad . \quad . \quad (39)$$

where I denotes the steady current in the primary. Similarly integrating over the break, we get

$$\int j dt=+\frac{M}{S}I=\frac{ME}{SR},$$

In the second place, if we assume the break instantaneous, we can find the initial value of the direct current in S. Thus integrate[2] (38) from the instant before break to the time τ after it, τ being infinitely short compared with the duration of the induction currents, then

$$-MI+Nj_0+S\int_0^\tau j dt=0.$$

Now the last term may be neglected, because τ is infinitely small and j is not infinite, hence we have, for the initial value of j,

$$j_0=\frac{M}{N}I=\frac{ME}{NR}. \quad . \quad . \quad . \quad . \quad . \quad (40)$$

It is very easy now to determine the farther course of the current in S. The equation for j reduces to

$$N\frac{dj}{dt}+Sj=0;$$

and we get, using (40),

$$j=\frac{ME}{NR}e^{-\frac{S}{N}t}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (41)$$

The direct induced current (current at break), therefore, starts in our ideal case with an intensity which is to the intensity of the steady current in the primary as the coefficient of mutual induction of the coils is to the coefficient of self-induction of the secondary, and then dies away in a continuous manner like any other current left to itself in a circuit of given resistance and self-induction.

Since we have already given enough of these calculations to serve as a specimen, we content ourselves with stating the result for the current at make. Owing to the self-induction of R, etc., the current in R rises continuously from zero to the value I; the induced current in S therefore begins also from zero, rises to a maximum, and then dies away. The mathematical expression for it contains, as might be expected, *two* exponential terms.

Electro-kinetic energy.

It is instructive, in connection with what has already been said concerning the electro-kinetic energy of two moving circuits, to examine what becomes of the energy in the case of two fixed circuits of invariable form.

Equations (37) and (38) may be used if, for generality, F be written instead of 0 in (38), so that there is electro-motive force (say of constant batteries) in both circuits. Multiplying (37) by i and (38) by j, adding and integrating from the time before E and F begin to act to a time τ when the currents have all become steady, we get

$$\int_0^\tau(Ei-Ri^2)dt+\int_0^\tau(Fj-Sj^2)dt=\tfrac{1}{2}(Li^2+2Mij+Nj^2). \quad (42)$$

In words, the *excess* of the chemical energy exhausted in the batteries over the amount of energy which appears as heat in the circuits is $\frac{1}{2}(Li^2+2Mij+Nj^2)$ which we denote by K. Similar remarks to those made at p. 72 apply here. K is the amount of electro-kinetic energy stored up in the medium surrounding the circuits during the time that E and F are raising the currents against self and mutual induction.

If we integrate similarly over the break of both currents, we find the *defect* of the chemical energy exhausted under the heat evolved in the circuit to be again K. Much of the energy thus discharged from the system at break usually appears in the spark.

---

[1] *Pogg. Ann.*, 1851.

[2] The reader might suppose that this process of integration might be equally applied to (37). This is not so, however, owing to the variability of R at the break.

Electrical oscillations.

Electrical Oscillations.—Helmholtz[1] seems to have been the first to conceive that the discharge of a condenser might consist of a backward and forward motion of the electricity between the coatings, or of a series of electric currents alternately in opposite directions. Sir William Thomson[2] took up the subject independently, and investigated mathematically the conditions of the phenomenon.

Thomson's theory.

Let q be the charge of the condenser at time t, C its capacity, E the difference of potentials between the armatures, i the current in the wire connecting the armatures, R its resistance,[3] L the coefficient of self-induction. Then we have

$$q = \mathrm{CE}, \quad i = -\frac{dq}{dt},$$

and

$$\mathrm{L}\frac{di}{dt} + \mathrm{R}i = \mathrm{E},$$

i.e.,

$$\frac{d^2q}{dt^2} + \frac{\mathrm{R}}{\mathrm{L}}\frac{dq}{dt} + \frac{1}{\mathrm{LC}}q = 0 \quad . \quad . \quad . \quad . \quad . \quad (43)$$

The solution of this equation is

$$q = e^{-mt}(\mathrm{A}e^{nt} + \mathrm{B}e^{-nt}), \quad . \quad . \quad . \quad . \quad (44)$$

where

$$m = \frac{\mathrm{R}}{2\mathrm{L}}, \ n = \sqrt{\frac{\mathrm{R}^2}{4\mathrm{L}^2} - \frac{1}{\mathrm{LC}}}.$$

A and B are constants to be determined by the conditions $q = \mathrm{Q}$ and $\frac{dq}{dt} = 0$ when $t = 0$.

Two distinct cases arise.

(1.) Let R be greater than $\sqrt{\frac{4\,\mathrm{L}}{\mathrm{C}}}$; then the expotentials in (44) are real, the discharge is continuous, all in one direction, and involves no essentially new features.

(2.) Let R be less than $\sqrt{\frac{4\,\mathrm{L}}{\mathrm{C}}}$; then the appropriate form of the solution is

$$q = e^{-mt}(\mathrm{A}\cos nt + \mathrm{B}\sin nt),$$

where m has the same meaning as before, but n stands now for $\sqrt{\frac{1}{\mathrm{LC}} - \frac{\mathrm{R}^2}{4\mathrm{L}^2}}$. If we determine A and B by the initial conditions, we get

$$q = e^{-mt}\left(\cos nt + \frac{m}{n}\sin nt\right)\mathrm{Q} \quad . \quad . \quad . \quad . \quad (45)$$

The current is given by

$$i = \frac{\mathrm{Q}}{\mathrm{NLC}}e^{-mt}\sin nt \quad . \quad . \quad . \quad . \quad . \quad . \quad (46)$$

It follows from these equations that, when $\mathrm{R} < \sqrt{\frac{4\,\mathrm{L}}{\mathrm{C}}}$, the charge of one armature of the condenser passes through a series of oscillations. The different maxima are

$$\mathrm{Q}, \qquad -\mathrm{Q}e^{-\frac{m\pi}{n}}, \ \mathrm{Q}e^{-\frac{2m\pi}{n}}, \ \mathrm{Q}e^{-\frac{3m\pi}{n}}, \text{ etc.},$$

occurring at times

$$0, \qquad \frac{\pi}{n}, \qquad \frac{2\pi}{n}, \qquad \frac{3\pi}{n}, \text{ etc.}$$

When the charge has any of these maximum values, the current is zero. The current maxima form a similar descending geometric series, the times of occurrence being

$$\frac{\theta}{n}, \ \frac{\theta + \pi}{n}, \ \frac{\theta + 2\pi}{n}, \ \frac{\theta + 3\pi}{n}, \text{ etc.},$$

where θ is the acute angle $\tan^{-1}\frac{n}{m}$.

The interval between any positive and the next negative maximum, whether of charge or current, is therefore $\frac{\pi}{n}$.

We need not insist on the evident importance of this result. Thomson, in his original paper, points out the various applications of which it is capable. He predicts the phenomenon afterwards observed by Feddersen; in fact, he suggests the use of Wheatstone's mirror to detect it. Its bearing on the anomalous magnetization of steel needles by jar discharges, and on the anomalous evolution of gas by statical discharges, when electrodes of small surface are used (in Wollaston's manner), are also dwelt upon.

Experiments of Feddersen, etc.

Several physicists have taken up the experimental investigation of this matter. Feddersen's experiments realize the case above discussed, if we abstract the disturbance owing to the air interval, of the effect of which it is not easy to give an accurate account. Feddersen's results are in good general agreement with theory. He finds, for instance, that the critical resistance at which the discharge begins to assume the oscillatory character varies inversely as the square root of the capacity of the battery from which the discharge is taken. A good account of the researches of Paalzow,[4] Bernstein,[5] and Blaserna, and of the older researches of Helmholtz,[6] remarkable for the use of his pendulum interruptor, will be found in Wiedemann, §§ 801, etc. Schiller, in a very interesting paper,[7] describes a variety of measurements of the period of oscillation, and the damping of the alternating currents in a secondary coil, when the current of the primary is broken. By means of the pendulum interruptor of Helmholtz (for description of which see his paper) the primary is broken, and at a measured interval thereafter the secondary circuit, which contains a condenser and a Thomson's electrometer, is also broken. The deflection of the electrometer indicates the charge of the condenser at the instant when the secondary is broken. The interval between two null points separated by a whole number of oscillations can thus be found, and hence the time of oscillation of the coil calculated. The agreement of Schiller's results with calculation is very remarkable, and must be regarded as a highly satisfactory proof of the validity of the theoretical principles involved.

Induction in masses of metal.

Induction in Masses of Metal and Magnetism of Rotation.—Hitherto we have dealt only with linear circuits; but it is obvious that currents will also be induced in a mass of metal present in a varying magnetic field. If the variation of the field be due to relative motion between the mass of metal and the system to which the field is due, the electro-magnetic action of the induced currents will oppose the motion. Many instances might be given of this principle. If a magnet be suspended over a copper disc, or, better still, in a small cavity inside a mass of copper, its vibrations are opposed by a force due to the induced currents which for small motions varies as the angular velocity of the needle. Accordingly, it comes much sooner to rest than it would do if suspended in the air at a distance from conducting masses; it moves beside the copper as if it were immersed in a viscous fluid. Plücker suspended a cube of copper between the poles of a powerful electro-magnet, and set it spinning about a vertical axis; directly the magnet was excited it stopped dead. Foucault arranged a flat copper disc between the flat poles of an electro-magnet placed at such a distance apart as just to admit it between them. The disc was set in rotation by means of a driving gear. So long as the magnet was not excited, the driver had comparatively little work to do; but as soon as the magnet was excited, the work required to keep up any considerable velocity greatly increased. The additional work thus expended appears in the heat developed in the disc by the induced currents. Tyndall demonstrates this very neatly by causing a small cylindrical vessel of thin copper filled with fusible metal to rotate between the poles of an electro-magnet, when enough heat is quickly developed to melt the metal.

Experiments of Plücker and Foucault.

Arago's experiment.

On the other hand, when a mass of metal moves in the neighborhood of a magnet, the electro-magnetic action of the induced currents will cause the magnet to move, if it be free to do so. Thus, if we suspend a magnet with its axis horizontal over a disc which can be set in rotation about a vertical axis, owing to the electro-magnetic action of the induced current, the needle will tend to rotate in the same direction as the disc. If the velocity be great enough, or the needle be rendered astatic, it may be carried round and round continuously. This action was discovered by Arago, and excited the attention of many philosophers, till it was at last explained by Faraday (see Historical Sketch). Many of the observations made by Faraday's predecessors, and some made by himself, are at once seen to support the conclusion that the phenomenon is

Faraday's explanation.

[6] *Monatsber. der Berl. Akad.*, 1874.

[7] *Pogg. Ann.*, 1874.

simply a case of Lenz's law. Thus Snow Harris found that the deflecting couple on a suspended needle varied approximately as the velocity of the disc directly, and as the square of the distance of the needle from the disc inversely. It was also found that the action of the disc was directly proportional to the conductivity of the metal of which it was made, an exception occurring in the case of iron, whose action was disproportionately great. Cutting radial slits in the disc diminished the action very much.

Besides the component tangential to the disc, it is found that there is a repulsive normal action on the pole of the magnet, and also a radial action, which may be towards or from the centre of the disc, according as the pole is nearer or farther from the centre of the disc. These actions look at first sight somewhat more difficult to explain; but a little consideration will show that the laws of induction account for these also.

Let us first suppose the induced currents to appear and die away instantly after the small motion of the disc which produces them (we may suppose the motion of the disc to take place by an infinite number of small jumps). Thus the currents of induction are obviously symmetrical with respect to the diameter through the foot of the perpendicular from the magnetic pole on the disc, and we may roughly represent the electro-magnetic action by a magnet placed perpendicular to the diameter at a certain distance from the centre of the disc, its south pole pointing in the direction of the disc's motion if the inducing pole be a north pole. Let OX (fig. 52) be the direction of the diameter in the same vertical plane as the pole, NS the representative magnet, OY being the direction of motion. By our present supposition the inducing pole M lies in the plane of ZOX, in which case it is obvious that the resultant action reduces to a tangential component T parallel to OY.

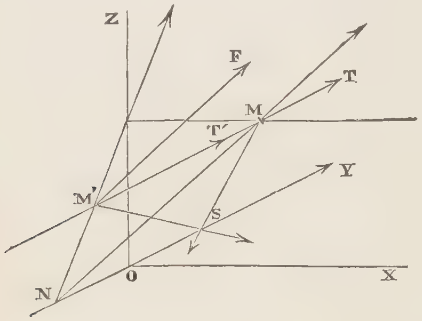

Fig. 52.

But, owing to the inductive action on each other of the currents in the disc, the induced currents do not rise and fall instantaneously, but endure for a sensible time. We may roughly represent the effect of this by supposing the representative magnet NS carried onwards a little with the disc, or, which amounts to the same thing, we may suppose the pole M to lag a little behind at M′ (lying, say, on MM′ perpendicular to ZOY). The action of N will now preponderate, and the resultant force on M′ will be in the direction M′F. This force, when resolved parallel to OY, OZ, OX, gives a tangential component as before, a repulsive normal component, and a radial component, which will be directed to or from the centre of the disc, according as the representative magnet lies farther from or nearer to the centre of the disc than the foot of the perpendicular from M′.

The original explanation of rotation magnetism (Faraday, *Exp. Res.*, 81, etc.) should be consulted by the reader who wishes to pursue the subject. An account of the researches of Nobili, Matteucci, and others will be found in Wiedemann, Bd. ii. § 860, etc. The mathematical theory has been treated by Jochmann, who neglected the inductive action of the currents on each other (*Crelle's Journ.*, 1864; *Pogg. Ann.*, 1864; also Wiedemann, *l.c.*). A complete theory of the induction of currents in a plane conducting sheet has been arrived at by Maxwell by means of an extremely elegant application of the method of images (*Proc. R. S.*, 1872; also *Electricity and Magnetism*, vol. ii. §§ 668, 669).

On the Origin of Electro-motive Force.

It remains for us now to view the transformations of energy which take place in the voltaic circuit from the other side, and to inquire whence comes the energy that is evolved in so many different forms by the electric current. Two distinct questions are here involved. First—What form of energy is being absorbed, and at what part of the circuit does the absorption take place? Secondly—Where is the electro-motive force which drives the current situated?

Conservation of energy.

To the first of these questions experiment has given, on the whole, a very satisfactory answer. The electric circuit is, indeed, one of the best instances of the great law of conservation, which states that the appearance of energy anywhere is always accompanied by the disappearance somewhere of energy to an equal amount. No general discussion of this first question is necessary; it will be sufficient to indicate the application of the general principle when we deal with particular instances.

Unfortunately the answers, both experimental and theoretical, that have been at different times given to our second question, are not so concordant as could be desired. The reader is, therefore, cautioned against accepting without due examination[1] anything that may be here advanced.

Contact force.

Perhaps the most general principle concerning the origin of electro-motive force recognized by physicists of the present day is the following:—

When two different substances are in contact, there exists in general an electro-motive force at the surface of separation, tending to displace electricity across that surface.

This electro-motive force is commonly called the "electro-motive force of contact," or simply the "contact force." In the particular case of two conductors in contact, the effect of this force would simply be to maintain a certain difference of potential between them.

Although the earliest known case of electrification—viz. amber rubbed with woollen cloth—is an instance in point, and although many experiments on electrification by the friction of different substances were made, yet this principle was not recognized fully till the experiments of Galvani and Volta directed the attention of men of science to the matter.

Contact of metals. Volta's experiments.

Volta was the first to demonstrate clearly the existence of the contact force in the case of metals. A simplified form of his fundamental experiment is the following. The upper and lower plates of a condensing electroscope (see above, p. 31) are made of different metals, say copper and zinc. Let the upper plate be laid upon the lower, and the metallic contact ensured by connecting them for an instant by means of a wire. If the upper plate be now lifted vertically upwards, the gold leaves of the electroscope diverge, indicating that the zinc plate is now positively electrified to a considerable potential. This is explained as being due to the contact force at the junction of the copper wire with the zinc plate, by virtue of which the zinc is at a higher potential than the copper. Suppose the upper plate to be connected with the earth, then if E be the contact force, the potential of the zinc plate is E. Now E is very small, but as soon as the upper plate is raised the potential of the lower plate is increased in the same ratio as its capacity is diminished; hence the divergence of the leaves.

Law of Volta.

Volta found that he could arrange the metals in series, thus—

Zn...............	0	Fe...............	1
Pb...............	5	Cu.	2
Sn...............	1	Ag	3

such that, when any metal is placed in contact with one below it in the series, it takes a higher potential; and he found that the electro-motive force between any two metals in the series is the sum of the electro-motive forces between every adjacent intervening pair. Thus if Zn|Pb denote the electro-motive force from lead to zinc, we get from the above table,

$$\mathrm{Zn}|\mathrm{Pb}=5,\ \mathrm{Pb}|\mathrm{Sn}=1,$$
$$\mathrm{Zn}|\mathrm{Sn}=\mathrm{Zn}|\mathrm{Pb}+\mathrm{Pb}|\mathrm{Sn}=6,$$
$$\mathrm{Pb}|\mathrm{Cu}=\mathrm{Pb}|\mathrm{Sn}+\mathrm{Sn}|\mathrm{Fe}+\mathrm{Fe}|\mathrm{Cu}=6,$$

and so on.

It follows from Volta's law that, if a number of metals be connected up in series, the difference of potentials between the extreme metals is independent of the intermediate metals, and, in particular, is zero if the extreme metals be the same. We cannot, therefore, have a resultant electromotive force in a closed circuit consisting of metals merely. This is entirely in accordance with experiment, provided the temperature be the same everywhere.

---

[1] This applies particularly to any indications of the views of living physicists.

Experiments by Kohlrausch.

While one party of physicists neglected or attempted to explain away Volta's contact force, another took up the investigation, and endeavored to obtain precise measurements of it in different cases. Careful experiments of this kind were made by Kohlrausch[1] and Gerland,[2] by a method due to the former.

A condenser is used whose plates are made of the metals to be tested, say zinc and platinum. The plates are first placed parallel to each other at a very small distance apart, and touched simultaneously with a wire (say of platinum). A difference of potentials is thereby established, so that if the potential of the Pt be zero that of the Zn is Zn Pt. (Here we neglect the contact force between air and zinc and between air and platinum. No experimental proof that we know of has been given in support of this, see below, p. 80.) In consequence of this difference of potentials the Zn plate becomes positively charged. The wire is now removed, the plates of the condenser separated to a considerable distance, and the Zn plate connected with one electrode of a Dellmann's electrometer, the other electrode of which is connected to earth. The reading is proportional to the potential difference Zn|Pt increased in the ratio in which the capacity of the Zn plate has been decreased by the separation. Hence, if A be the reading,

$$\mathrm{Zn|Pt} = \lambda \mathrm{A} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The condenser plates are now brought into their former position, and connected through a Daniell's cell, consisting of a strip of zinc immersed in a porous vessel filled with zinc sulphate, which is itself immersed in a vessel containing copper sulphate, into which dips a strip of copper. In the first instance, the copper strip is connected with the zinc plate, and the zinc strip with the copper plate of the condenser. The difference between the potentials of the condenser plates is easily found by an application of Volta's law[3] to be D + Zn|Pt, where D denotes the difference between the potentials of the two pieces of *copper* forming the terminals of a Daniell's cell; hence if B be the electrometer reading, after removing the Daniell and separating the plates as before, we have

$$\mathrm{D} + \mathrm{Zn|Pt} = \lambda \mathrm{B}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

If we connect up the Daniell the opposite way with the condenser, then we get a reading C, such that

$$\mathrm{D} - \mathrm{Zn|Pt} = \lambda \mathrm{C}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

From (2) and (3) we get

$$\mathrm{Zn|Pt} = \frac{\mathrm{B}-\mathrm{C}}{\mathrm{B}+\mathrm{C}}\mathrm{D}, \quad . \quad . \quad . \quad . \quad . \quad (4)$$

which gives the contact force Zn|Pt in terms of the electromotive force of a Daniell. From (1), (2), (3) we get

$$\mathrm{B} - \mathrm{C} = 2\mathrm{A},$$

an identical relation which the observations ought to satisfy, and which, therefore, affords the means of testing their accuracy.

In this way Kohlrausch found for Zn|Cu the value ·48D, or, in other words, that the contact force from copper to zinc is about equal to half the electro-motive force of a Daniell's cell. As an instance of the general nature of the results, we give two series of numbers from the observations of Kohlrausch. The contact force is between zinc and the metal mentioned in first column in each case, and Zn|Cu is taken = 100.

Cu	100	100
Au	112	115
Ag	105	109
Pt	106	123
Fe	75	—

In the second set of experiments the metals were carefully cleaned, whereas in the first set they may have been a little oxidized. This may very well account for the differences, for Kohlrausch found oxidized zinc strongly negative[4] to freshly cleaned zinc. In fact, he found Zn|ZnO = about ·4Zn|Cu.

In order to test Volta's law, a further series of observations was made, giving the contact force between iron and several metals. The following table gives the results observed directly and calculated from the table last given:—

	Observed.	Calculated.
Cu	31·9	25·3
Pt	32·3	32·3
Au	39·7	38·0
Ag	29·8	30·9

It will be seen that, with the exception of the values for Fe|Cu, the agreement is very fair.

Gerland and Hankel.

It is not necessary to give here the results of Gerland and Hankel.[5] The latter made a great number of very careful experiments. He showed that the results depend on the nature of the surface of the bodies, being different when the surface is filed and when it is polished with rouge or other powder. His tables also show the gradual change effected in the contact force when the plates are exposed to the action of the air.

Liquids and metals.

According to Volta, the contact forces between metals and liquids are either very small, and do not follow the same law as the contact forces between metals, or else are absolutely non-existent. Subsequent observers, however, demonstrated the existence of contact forces in this case also, but showed that they do not obey Volta's law like the contact forces in the case of metals.

Becquerel, etc.

Becquerel[6] placed the fluid to be examined in a capsule of the metal, say copper. The capsule was placed on the upper plate of a condenser consisting of two copper plates in connection with a gold-leaf electroscope. The fluid and the lower plate of the condenser were touched each with a finger for a short time, and then the upper plate was removed. The divergence of the gold leaves was taken to indicate the contact force. In this way Becquerel found that zinc, copper, and platinum were mostly negative to alkaline solutions; but the metals were in general positive to concentrated sulphuric acid. It is obvious, however, that the result of the experiment is complicated by the contact of the hand with the liquid and with the metal of the condenser.

Similar objections apply to the results of Pfaff[7] and Peclet.[8]

Buff[9] made the lower plate of his condenser of the metal to be examined, of zinc for example; upon this was laid a thin glass plate on which was spread a thin layer of the liquid to be examined, or a piece of filter paper soaked with it. A zinc wire was used to bring the liquid and the lower plate of the condenser into communication; this wire was then removed and the glass plate with the liquid lifted. The divergence of the leaves was taken to indicate the contact force between zinc and the liquid. Although this method is an improvement on the methods of Becquerel and Peclet, it is still unsatisfactory, owing to the presence of the glass.

Hankel's method.

The most extensive and at the same time most careful experiments at present on record are those of Hankel.[10]

The fluid (L) to be examined was placed in a wide-mouthed funnel. The condenser was formed by the surface of the liquid and a copper plate, which could be placed parallel to it at a very short distance apart, and raised as usual. The stem of the funnel was bent at a right angle twice, and ended in a wider portion, into which dipped a strip of the metal (M) to be examined. M was connected for a moment by a platinum wire with the copper plate and also with the earth. The wire was then removed, the plate was raised, and its potential determined by means of Hankel's dry pile electroscope. The reading (A) is proportional to $Cu|Pt + Pt|M + M|L$, or, by Volta's law to $Cu|M + M|L$. Hence

$$Cu|M + M|L = \lambda A.$$

In the next place, the funnel is emptied and a plate of the metal M placed on its mouth. The copper plate is lowered so that it is at the same distance as before, contact established by means of the platinum wire, and so on. The reading being B, we have

$$Cu|M = \lambda B.$$

The plate of M is replaced by a plate of zinc, and the experiment repeated, and we have, C being the third reading,

$$Cu|Zn = \lambda C.$$

From these three results we get

$$M|L = \frac{A - B}{C} Cu|Zn.$$

It is not necessary to quote Hankel's results here. The reader may refer to Wiedemann's *Galvanismus*, or to Hankel's paper.

Thomson's demonstration of contact force.

Sir William Thomson has given a new proof of the existence of Volta's contact force as follows.[1] A ring is formed, one-half of which is copper, the other half zinc. This ring is placed horizontally, and a needle made of thin sheet metal is so balanced as to form a radius of the ring. If when the needle is unelectrified it be adjusted so as to be over the junction of the two metals, then, when it is positively electrified, it will deviate towards the copper, and when negatively electrified, towards the zinc. Again, if a whole, instead of a half needle as above, be suspended over a disc made of alternate quadrants of zinc and copper, or, better still, inside a flat cylindrical box constructed in a similar way, so that when the needle is unelectrified its axis coincides with one of the diameters in which the disc is divided, then when the needle is positively electrified it will take up a position such that its axis bisects the copper quadrants; if it be negatively electrified, its axis will bisect the zinc quadrants.

Thomson has also given an elegant demonstration of the contact force between copper and zinc by means of an apparatus which is a modification of his water-dropping apparatus.[2] A copper funnel is placed in a cylinder of zinc, and drops copper filings at a point near the centre of the cylinder. The filings are charged negatively by induction as they fall, owing to the excess of the potential of the zinc cylinder over that of the copper. If therefore the filings be caught in an insulated metal can, they will communicate to it a continually increasing negative charge, while the zinc cylinder and the copper funnel will become charged more and more positively.

Thomson finds, in agreement with Kohlrausch, that, when the copper and zinc are bright, the electro-motive force of contact is about half that of a Daniell's cell. When the copper is oxidized by heating in air, the contact force is equal to a Daniell or more. He has gone a step farther, and shown that when two bright pieces of copper and zinc are connected by a drop of distilled water, their potentials are as nearly as can be observed the same.[3]

Clifton.

The subject of contact electricity has been taken up quite recently by Clifton.[4] He experiments on the contact force between a metal and a liquid by a method which is a simplification of Hankel's.

Two horizontal plates are used of the metal M; the liquid L is placed in a glass vessel on the lower plate and connected with the lower plate by a strip of the same metal which dips into it. The upper plate is lowered to a distance of 0·1 or 0·2 mm. from the surface of the liquid, which acts as the lower surface of the condenser, and the upper plate and lower plate are connected by a copper wire. The difference of potential between the two surfaces of the condenser is therefore $M|L$. The copper wire is then removed, the upper plate raised, and its potential measured with a Thomson's electrometer. In this way a contact force equal to the thousandth part of $Zn|Cu$ can be detected.

Clifton finds zinc and copper to be both positive to water to about the same degree, and both very slightly negative to dilute sulphuric acid. He concludes therefore that zinc and copper dipping in water will be at the same potential. This he verifies directly, finding that any difference of potential, if it exist, must be less than ·00079 of the electro-motive force of a Daniell. The result of Sir William Thomson is therefore confirmed.

There are many other points of interest in Clifton's paper, but, as the results are given in most instances as preliminary, we need not discuss the matter farther.

Source of uncertainty.

Before leaving this subject, it may be well to notice that there is one point which is not touched by all these experiments, viz., the question whether there is or is not a contact force between metals or even liquids and air. It has not yet been shown that the results of the experiments which are supposed to demonstrate that $Zn|Cu$ is about half the electro-motive force of a Daniell could not be equally well explained by supposing the difference of potential to be[5] $Cu|A + A|Zn + Cu|Zn$, whence $Cu|Zn$ is very small compared with $Cu|A$ and $A|Zn$. This supposition would not invalidate Volta's law; nor would it contradict Clifton's results, for we have, in accordance with his experiments, on the new hypothesis,

$$Aq|A + Cu|Aq + Aq|Cu = Aq|A + Zn|Aq + A|Zn,$$

therefore, transposing,

$$Zn|Aq + Aq|Cu + Cu|A + A|Zn = 0,$$

which, according to the new hypothesis, means that copper and zinc immersed in water are at the same potential. In this view, the important part of the contact force usually observed between zinc and copper would be $Cu|A + A|Zn$,[6] which must therefore, by Sir Wm. Thomson's result, be the same as $Cu|Aq + Aq|Zn$.

It is not very easy to see how this point is to be settled by direct measurements of electro-motive force. Supposing, however, that it were settled, and that the contact force between two given metals A and B, and between each of them and a given liquid L, were known, then the difference of potentials between the two metals when immersed in any liquid could be predicted in all cases, and also the initial electro-motive force tending to send a current through a circuit made by connecting the metals together and dipping them into the liquid.

Gerland's results.

A number of cases of this kind have been investigated by Gerland;[7] but satisfactory agreement between theory and observation has been attained in but a few cases. Researches of this kind are beset with a double array of almost insuperable difficulties.

The direction of the initial resultant electro-motive force in any circuit of two metals and one fluid may be found by observing the first swing of a galvanometer through which the circuit is suddenly connected. Considerable precautions must be taken to obtain consistent results, and when all care has been taken, it is not found that the results of one observer always agree with those of another. This is scarcely to be wondered at, when we consider the difficulty of making sure that in two different experiments we are operating with absolutely the same metals and fluid in absolutely the same conditions as to surface.

When the current tends to pass from one metal to another through the liquid in which they are immersed, the former metal is said to be positive to the latter. If the whole electro-motive force in the circuit be the sum of all the contact forces at the various junctions, then it follows easily that we ought to be able to arrange the metals in a series, such that any one in the series is positive to any following one and negative to any preceding when both are dipped in the same liquid. It does not follow that the order of the series is the same for different liquids; this would be so if the metallic contacts alone were operative.

Electro-motive series. Two metals and one liquid.

Many electro-motive series of this kind have been given by different experimenters; but they have lost much of their interest now that the theory of metallic contact, pure and simple, is given up. The following set is given by Faraday:—[8]

[7] See Wiedemann, Bd. i. § 36.

[8] *Exp. Res.*, 2012.

HNO_3 (dil.).	H_2SO_4 (dil.).	HCl.	HNO_3 (strong).	KHO.	KHS.	K_2S_5.
Ag	Ag	Sb	Ni	Ag	Fe	Fe
Cu	Cu	Ag	Ag	Ni	Ni	Ni
Sb	Sb	Ni	Sb	Cu	Bi	Bi
Bi	Bi	Bi	Cu	Fe	Pb	Sb
Ni	Ni	Cu	Bi	Bi	Ag	Pb
Fe	Fe	Fe	Fe	Pb	Sb	Ag
Sn	Pb	Pb	Sn	Sb	Sn	Sn
Pb	Sn	Sn	Pb	Cd	Cu	Cd
Cd	Cd	Cd	Zn	Sn	Zn	Cu
Zn	Zn	Zn	Cd	Zn	Cd	Zn

It will be seen that the order of the metals is not the same for different liquids.

Contact of two liquids.

Just as between different metals and between metals and liquids there is a contact force, so there is a contact force between different liquids. The *direct* observations of this contact force are very few and uncertain. One thing, however, is settled, viz., that the contact forces between liquids do not universally at least obey the law of Volta, or, at all events, do not form a consistent series with the metals; for a great variety of circuits of one metal and two solutions have been discovered in which the resultant initial electro-motive force is not zero. Faraday[1] has even found cases of this kind with one metal and two different strengths of the *same* solution.

The cell of Becquerel is a favorite illustration of such a circuit. It consists of a porous vessel filled with a solution of potash and immersed in a beaker containing nitric acid; two strips of platinum immersed in the potash and nitric acid respectively form the plates. The current goes in the cell from the potash to the nitric acid. The following additional examples are taken from Wiedemann.[2]

One metal and two liquids.

The current flows from the metal through the liquids in the order named to the same metal again. For brevity, the metal is named only once.

Metal.	1st Fluid.	2d Fluid.
Pt	KHO	Acids
Pt	$CuSO_4$	Dil. H_2SO_4
Pt	NaCl	$ZnCl_2$
Pt	NH_3	$CuSO_4$
L	$CaCl_2$	Dil. HNO_3
M	Conc. H_2SO_4	HNO_3
R	KCy	HNO_3

L stands for Zn, Cu, or Pt.
M " Cu, Fe, Pb, Sn, or Ag.
R " Ni, Bi, Pt, Hg, Pd, Sb, Fe, C, Ag, Zn, Cu, Cd, or Sn.

Two metals and two liquids.

A great variety of active voltaic circuits have been formed with two liquids and two metals. The best known class of cases is that in which the metals are in contact, as in the two-fluid batteries of Daniell, Grove, and Bunsen. But Faraday[3] gives a list of some thirty cases in which the fluids and metals are placed alternately, so that there is no metallic contact. He marks the following combinations as powerful:—

Iron	Diluted nitric acid.	Platinum	Green nitrous acid.
Do.	Hydrochloric acid.	Do.	Do. do.
Do.	Solution of com. salt.	Do.	Do. do.
Copper	Potassium sulphide.	Iron	Dil. nitric acid.
Do.	Strong nitric acid.	Do.	Do. do.

Measurements of electro-motive force.

It must be carefully noticed that the galvanometer indication in the first instant only is to be considered. After the first rush of electricity the direction even of the current may alter. Above all, no conclusion concerning the value of the initial electro-motive force is to be drawn from measurements of the subsequent current. Quantitative determinations of the electro-motive force in many of the above cases have been made by various methods, of which an account will be found in Wiedemann's *Galvanismus*, Bd. i. § 230. The most convenient plan is to use Thomson's quadrant electrometer, Lippmann's capillary electrometer or some other instrument which allows us to measure the electro-motive force while no current is passing through the cell. The galvanometer may also be used as in Latimer Clark's modification of Poggendorff's compensation method.

Method of Poggendorff and Latimer Clark.

The apparatus may be arranged according to the scheme in fig. 53. ABC denotes part of the resistance in the circuit of the battery K; the circuits *Ap*ELB, *Aq*FMC each contain a galvanometer, a cell, and a key. The cells E and F are so arranged as to *tend* to send currents in the same directions as K, but the resistances AB, AC are so adjusted that when the key L or the key M is depressed, no current is indicated by *p* or *q*. When this is so, we must obviously have $E = V_A - V_B$, $F = V_A - V_C$, etc., V_A, V_B, V_C denoting the potentials at A, B, and C. Hence, if P, Q, R denote the resistances in AB, AC, and in the whole circuit of K,

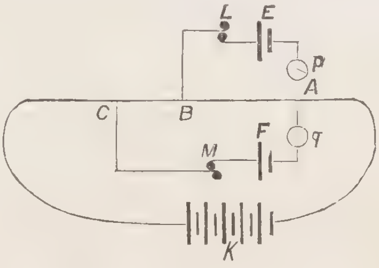

Fig. 53.

$$E = \frac{P}{R}K, \quad F = \frac{Q}{R}K.$$

If K were a constant battery, and its internal resistance were either known or else so small as to form only an inappreciable fraction of R, then each of the equations just written might be used singly, and we might operate with one cell and one galvanometer, comparing the electro-motive force of the cell with K. In general, however, this will not be possible, and then we have, eliminating K and R,

$$\frac{E}{F} = \frac{P}{Q},$$

from which we get the ratio of E to F independent of the variation of K and R. We can by this method therefore find the ratio of the electro-motive force of a given combination to that of a standard cell, when no current is passing through either. The process would be perfect in practice if a standard cell could be constructed whose absolute constancy could be relied on.

Contact force from polarization.—The flow of electricity through the cell is accompanied by a deposition of the products of chemical decomposition on the plates, which alters the surface contact forces. This constitutes the phenomenon of polarization, which we have already partially studied. It will be useful to consider a little more in detail some of the forms in which it is met with.

Varieties of polarization.

Transition resistance.

The products of electrolysis which accumulate at the electrodes may be simply held in solution or precipitated, or they may combine chemically with the solution; they may be deposited as a crust on the electrode, or they may enter into more or less intimate connection with it. Several of these different effects may occur together; but in almost all cases the result is the same, viz., a great weakening of the current after the first instant or so. This weakening of the current might be due either to a transition resistance caused by the alterations at the electrodes, or to an opposing electro-motive force arising from the alteration of the contacts. The former was the explanation adopted in the earlier researches of Poggendorff and Fechner; but there can be no doubt about the existence of the latter effect, and Lenz showed that it was sufficient to account for the facts observed. It has been usual, therefore, to neglect the transition resistance altogether in the great majority of cases. It is certain, however, that it really exists in some instances. Consider the case of two electrolytic cells containing concentrated sulphuric acid, the electrodes being in the one copper plates, in the other platinum plates. Either of these cells inserted into a voltaic current will weaken the current, but for different reasons. In both cases hydrogen is freed at the negative electrode, and reduces sulphur from the strong acid, the effect of which is not great either way, for if the negative electrode be replaced by a fresh plate the weakening of the current remains. At the positive electrode oxygen is evolved, which oxidizes the copper in the one case and is deposited on the platinum in the other,—in both cases replacing the positive electrode by a fresh plate will cause momentary increase in the current; but the copper plate which served as positive electrode if tested against a fresh copper plate gives very little return current, whereas the positive platinum plate similarly tested gives a very powerful one. In the one cell the weakening of the current was due to the resistance of a crust of non-conducting copper oxide, in the other it was due to the contact force at the surface of the oxygenated platinum.[1]

---

[1] *Exp. Res.*, 1975. [2] *Galvanismus*, Bd. i. § 63. [3] *Exp. Res.*, 2020.

Gas polarization.

The polarization which arises from the deposition of gas on the electrodes is, if we except the case where peroxides are formed, by far the most powerful form, and has been much studied ever since voltaic batteries were used. Experiments like the one just quoted prove decisively that the electro-motive force has its seat at the surface of the electrode itself, and is due to local alterations there. The certainty of this fact gives the study of the phenomenon great theoretical importance, since we may hope thereby to arrive at some idea of the nature of the contact force.

It is also certain that in most cases each electrode contributes separately to the whole electro-motive force, for if we remove the polarized plates the adhering gas goes with them, and each plate is found to be electrically different when tested against a fresh or unpolarized plate. We may also take measures to remove the deposited gas by washing the plates with water, potash, or nitric acid, or by igniting them; and it is found that the more energetic the chemical agency thus employed the more thoroughly is the polarization destroyed.

It seems clear, therefore, that it is the mere fact of the presence of the gas on the electrode in some form or other which causes the electrical difference. We may go still further and produce the phenomenon by depositing gas by means other than electrolytic. If a piece of platinum foil be immersed in hydrogen it absorbs the gas, as has been shown by Graham. A piece of foil thus treated is positive to a piece of freshly ignited foil when both are placed in dilute sulphuric acid. The same result is obtained by saturating the liquid in the neighborhood of the foil with hydrogen.[2] The activity thus conferred on the plate may be again destroyed by immersing it in chlorine or bromine, or even in oxygen, by igniting it, and so on. Similarly, if we dip a fresh piece of foil into chlorine or bromine, it will become negative to a fresh plate. The effect obtained by dipping the foil in oxygen in the ordinary state is very small, the oxygen deposited by electrolysis must therefore be in a different state to that condensed during mere immersion in the gas. This is probably due to the fact that electrolytically generated oxygen contains ozone (see art. ELECTROLYSIS); and in accordance with this we find that a platinum foil ozonized by being held in the electric brush proceeding from a charged conductor, or rubbed with phosphorus, is negative to a fresh plate in dilute sulphuric acid.

Grove's gas battery.

The gas battery of Grove is a remarkable instance of the electro-motive properties of gas-coated metals. Two long glass tubes A and B are arranged in the two necks of a Woulfe's bottle. The upper ends of the tubes are closed, but pierced by two platinum wires, to which are fastened two long strips of platinum foil (which are sometimes platinized)[3] reaching to very near the lower ends of the tubes. The bottle and part of the tubes are filled with some liquid, say dilute sulphuric acid, and hydrogen introduced into B and oxygen into A. This may be very conveniently done by sending an electric current from A to B and decomposing the dilute acid, but it may be done in other ways as well. This arrangement has an electro-motive force comparable with that of a Daniell's cell (see below, p. 82), and if the original volume of hydrogen in B be twice that of the oxygen in A it will continue to send the current through a closed circuit, the gas gradually disappearing in the tubes until none is left, when the current stops. These gas elements may be connected up in series, etc., and used like ordinary battery cells.

If the tube B be filled with ordinary hydrogen and A with liquid only, a current in the same direction as before is observed; but the liquid in A is decomposed and hydrogen evolved, which produces an opposing electro-motive force and stops the current. If A contain oxygen and B fluid only, the current lasts for a very short time unless the oxygen contain ozone. This is in accordance with what we have already seen.

Grove[4] has given an electro-motive series for the different gases and metals as follows:—

Chlorine.
Bromine.
Iodine.
Nitric oxide.
Carbonic acid.
Nitrogen.
Metals which do not decompose water.
Camphor.
Volatile oils.
Olefiant gas.
Ether.
Alcohol.
Sulphur.
Phosphorus.
Carbonic oxide.
Hydrogen.
Metals which decompose water.

In this series any member is positive to any preceding member.

Electrolytic convection.

We have already remarked that the polarization in many cases comes on very rapidly. In cases where the electro-motive force of the battery is not sufficient to produce a continuous evolution of gas, the current after the first rush dies away very rapidly. There are cases, however, in which a small current continues to flow for a very long time. Such currents are not accompanied by any visible evolution of gas, and it is clear that they could not be so accompanied, for, if the electro-motive force of the battery be under a certain limit, the amount of chemical energy absorbed by the current per unit of time is less than the intrinsic energy of the ions liberated in a unit of time. It was originally supposed, therefore, that, besides this electrolytic conduction proper, fluids conducted to a slight extent like metals. But Helmholtz[5] has shown that no such assumption is necessary, and has pointed out that when the fluid holds gas in solution a sort of electrolytic conduction may take place which involves, it is true, liberation of the ions, or at least of an ion, but *so* that the final result does not imply absorption of more energy than the battery can furnish per unit of time in accordance with Faraday's law of electrolytic conduction.

Suppose, for instance, that the dilute sulphuric acid in an ordinary voltameter held H in solution. When the current passes, O appears at the anode and unites with the H in solution to form water; a corresponding quantity of H is thereby liberated at the cathode, which is either absorbed by the platinum electrode or diffuses towards the anode, to combine in its turn with the appearing oxygen. It is obvious that the liberation of the ion in such a case does not involve absorption of energy to the extent necessary when both H and O are disengaged from water. A current might therefore be kept up under such circumstances for a long time by an electro-motive force under that of a cell of Daniell. Helmholtz has given the name of electrolytic convection to this species of electrolytic conduction. He has shown that the phenomenon comes to an end when the liquid is perfectly freed from gas. The absorption of the gases by the electrodes plays a great part here, and gives rise in gas-free liquids to a phenomenon analogous to the residual discharge. When the battery is first turned on, a rush of electricity takes place, then there is a small current which gradually dies away. The first rush is like the instantaneous charge of a condenser; the small current which arises from the slow penetration of the ions into the platinum corresponds to the formation of latent charge. When the voltameter is disconnected from the battery and discharged through a galvanometer, we have a first rush due to the part of the ions accumulated on the surface of the platinum, and then a gradually decreasing current due to the emergence of the gas which had penetrated into the metal. When the electro-motive force which presses the gas into the electrode is removed, the absorbed gas will move very nearly in accordance with the ordinary law of diffusion, and the rate of its reappearance will depend very little[6] on the electro-motive force at the surface of the electrode. Consequently the residual current furnished by such an apparatus will not depend on its external resistance. A sudden increase of the external resistance will simply cause the current to diminish until sufficient surface density has been attained to raise the electro-motive force to the value required to keep up the same current as before through the increased resistance; and the converse will happen if the external resistance be decreased.

This passage of the gas into the substance of the electrode has, at the instance of Helmholtz, lately been investigated by Root.[7] He finds that in certain cases, when only one side of a platinum foil is exposed to electrolysis, the deposited gas, whether H or O, actually passes through and produces the corresponding polarization on the other side of the foil.

---

[1] Wiedemann, Bd. i. § 455.

[2] See Macaluso's experiments, Wiedemann, *Nachträge*, § 53.

[3] This is best accomplished by washing the foils in hot nitric acid, and then using them to decompose a solution of platinic chloride with the current of two cells of Grove.

[6] Within certain limits, of course.

[7] *Pogg. Ann.*, 1876.

Maximum of polarization.

It might at first sight be expected that in all cases where the electro-motive force in the circuit is sufficient to produce continual evolution of the ions the polarization would be the same. This is not by any means the case, however, owing to the fact that the final state of the liberated ions varies with the strength of the current, or, more correctly speaking, with the *current density*, *i.e.*, the amount of electricity which crosses unit section of the electrode in unit time. When H_2 and O are being liberated from dilute H_2SO_4, this depends mainly on the formation of variable quantities of ozone and H_2O_2. This variation of the physical state and intrinsic energy of the liberated ions is a fact of the greatest importance in the art of electro-metallurgy. A better instance could not be given than Gore's electrolytic modification of antimony, whose intrinsic energy is strikingly manifested by its explosive properties.

The effect of enlarging the surface of the electrode in diminishing the polarization in the case where the maximum polarization is not reached was noticed above (p. 46). It has also the effect of diminishing the *maximum* of polarization in the case where the ions are completely set free. Platinizing has the same effect. Thus Poggendorff[1] found for the maximum polarization 2·12 to 2·32[2] for bright platinum plates, while it was only 1·83 to 1·85 for platinized plates. The effect of platinizing on the hydrogen and oxygen polarization was about equal for strong currents, but greater on the hydrogen polarization when the current was weaker. On the other hand, by using small platinum points to decompose water in Wollaston's manner, Buff[3] found the polarization as high as 3·31.

Poggendorff[4] and Crova[5] have investigated the dependence of the maximum of polarization on the current density. It follows from their researches that it can be represented by $A - B^{-aI}$, I being the current density.

It would appear that the maximum of polarization is decreased by increasing the temperature of the cell. The effect, however, in *some* cases at least which have been adduced to prove this, might be explained by the decrease of the internal resistance of the cell.

Agitating the electrodes, stirring the liquid in their neighborhood, or any other process which tends to dissipate the deposit on the electrode, leads, as might be expected, to a diminution of the polarization. The effect of increased pressure in retarding or helping electrolysis might be appreciable in certain cases. Suppose that an electro-chemical equivalent of the ions, during liberation under a pressure p, increases in volume by v, then during the passage of a unit of electricity work to the extent pv is done; the electro-motive force required to free the ions must therefore have a part equal to pv which may increase or decrease as the process goes on. If the ions be gases which obey Boyle's law very nearly, then pv is constant, so long as the temperature remains the same; so that we cannot expect, within reasonable limits, to check the electrolysis of dilute sulphuric acid by conducting it in a closed vessel.[6]

Rapidity of depolarization.

We have repeatedly drawn attention to the rapidity with which the polarization decays in the first few instants after the plates are connected through a circuit of moderate resistance. Direct proofs of this have been given by Beetz[7] and Edlund.[8] The former shows that the oxygen polarization decays much more rapidly than the hydrogen polarization, which is not to be wondered at, considering the greater readiness of platinum to absorb hydrogen; with palladium electrodes the difference would doubtless be still more marked. The reader may also consult an interesting paper on this subject by Bernstein[9] who concludes that in a certain case the polarization diminished by $\frac{1}{6}$ to $\frac{1}{10}$ of its value in about $\frac{1}{200}$ of a second.

There seems to be little reason to doubt the substantial accuracy of the facts just mentioned; and the reader will not fail to see the application to the theory and practice of the measurement of the electro-motive forces of inconstant electro-motors, a category under which, unfortunately for the electrician, all known voltaic batteries must be classed. The remark applies with double force to the measurement of the electro-motive force of polarization. Many measurements of the latter have been made. We quote a few, to give the reader a general idea of the magnitudes involved; into a discussion of the methods we cannot enter here.

Polarization in general.

Although the polarization by gas deposits has absorbed so much of the attention of physicists, it is by no means a solitary instance. The phenomenon is universal. It appears even with zinc plates in zinc sulphate, and copper plates in copper sulphate. The nearest approach to unpolarizable electrodes is the case of *amalgamated* zinc plates in zinc sulphate, originally discovered by Du Bois Reymond. When the sulphate solution is neutral, the polarization, as may be shown by immersing a large number of plates in series in the solution, is extremely small.

For an account of polarization at the surface of two liquids observed by Du Bois Reymond and other kindred matters, and for many other facts which we have passed over in silence, the reader may consult Wiedemann's *Galvanismus*. Some account will be found in the article ELECTROLYSIS of the remarkable phenomenon of the "passivity of iron, and of the powerful polarization arising from the formation of superoxides, on which depends the action of the secondary pile of Planté."

Application of the Laws of Energy to the Voltaic Circuit.—In the classical series of researches by which Joule laid the foundations of the laws of energy, a considerable share of attention is devoted to the energetics of the electric current. Guided by the great idea which he was gradually developing, Joule made experimental determinations of the amount of energy of various kinds evolved in the electric circuit. We have already seen how he measured the quantity of heat developed in a metallic conductor, and in an electrolyte.[1] This quantity was found to vary as the product of the resistance of the conductor into the square of the current strength, account being taken of disturbances at the electrodes in the case of electrolytes.

These disturbances were considered in the first memoir and allowed for. The accuracy of the view taken of them, to which Joule was led by the opinion of Faraday, that the solution of the oxide in the voltaic cell had no active share in producing the electric current, was justly questioned, implicitly by Sir Wm. Thomson[2] in 1851, and explicitly by Bosscha[3] in 1859.

Joule's results.

In a later memoir, however,[4] Joule made a direct experimental investigation of these secondary effects, and shows how they can be accounted for. His results have not been shaken by subsequent investigators; and the general conclusions to be drawn from them are not in the least affected by the theory of secondary action, which is suggested in the paper. These, so far as we are now concerned with them, are as follows:—

"1st. In an electrolytic cell there are three distinct obstacles to the voltaic current. The first is *resistance to conduction*; the second is *resistance*[5] *to electrolysis without chemical change*[6] [arising simply from the presence of chemical repulsion];[7] and the third is *resistance to electrolysis, accompanied by chemical changes.*

"2d. By the first of these (the resistance to conduction) heat is evolved exactly as it is by a wire, according to the resistance and the square of the current; and it is thus that a part of the heat belonging to the chemical actions of the battery is evolved. By the second a reaction on the *intensity*[8] of the battery occurs, and wherever it exists heat is evolved exactly equivalent to the loss of heating power in the battery arising from its diminished intensity. But the third resistance differs from the second, inasmuch as the heat due to its reaction is rendered latent, and thus lost to the circuit.

"3d. Hence it is that, however we arrange the voltaic apparatus, and whatever cells of electrolysis we include in the circuit, the whole caloric of the circuit is exactly accounted for by the whole of the chemical changes.

"4th. As was discovered by Faraday, the *quantity* of current electricity[9] depends upon the number of atoms which suffer electrolysis in each cell; and the intensity depends on the sum of chemical affinities. Now both the mechanical and heating powers of a current are (per equivalent of electrolysis in any one of the battery cells) proportional to its intensity. Therefore the mechanical and heating powers of the current are proportional to each other.

"5th. The magnetic electrical machine enables us to convert mechanical power into heat by means of the electric currents which are induced by it; and I have little doubt that, by interposing an electro-magnetic engine in the circuit of a battery, a diminution of the heat evolved per equivalent of chemical change would be the consequence, and this in proportion to the mechanical powers obtained."[10]

The above statement of Joule's contains, in a form which seems to us neither ambiguous nor *obscure*,[11] an exposition of the leading experimental principles of the energetics of the electric circuit. Besides the papers of Joule we have mentioned, two others on the electrical origin of the heat of chemical combination ought to be read in connection with this subject.[12] The now famous tract of Helmholtz, "Ueber die Erhaltung der Kraft," which appeared in 1847, shortly after these papers of Joule, did much, by its able statement of the issues, to advance this branch of electrical science, and should be consulted by every thorough student.

Favre's researches.

An extremely important contribution to the experimental evidence for the law of energy in the case of electric currents was furnished by the researches of Favre.[13] He uses a calorimeter, which is virtually a mercury thermometer with an enormous bulb, into which are inserted a number of test-tube shaped vessels all opening outwards. When a heated body is placed in one of these vessels its heat is quickly communicated to the mercury in the calorimeter, and the amount of heat thus communicated is measured by the expansion of the mercury, which is measured as usual by noting the displacement along a capillary tube. Into one of the recesses of the bulb of this calorimeter containing a quantity of dilute sulphuric acid was introduced 33 grm. of granulated zinc. The heat evolved during its dissolution was 18682 units (grammedegrees C.). Five of the recesses were then furnished with dilute sulphuric acid of the same strength as before, and into them were put five elements of Smee (amalgamated zinc and platinized copper). These were joined up in circuit by means of very thick copper wire, and the heat developed during the solution of 33 grm. of zinc observed as before. The result was 18674 units, *i.e.*, almost exactly the same as before. A small electro-magnetic engine was next introduced into the circuit, and the heat observed, first, when it was at rest; secondly, when it was in motion, but consuming all its energy in heat owing to friction, etc.; and thirdly, when it was doing work in raising a weight. The quantities of heat in the three cases were 18667, 18657, and 18374 units respectively. In the first four experiments, therefore, the heat developed in the circuit is sensibly the same, the mean being 18670; the heat developed in the last case is less than this by 296, which is the equivalent of the potential energy conferred on the raised weight. From this result the value of the mechanical equivalent of heat ought to be 443. This differs considerably from the best value (423 to 425), but not more so than might be expected from experimental errors.

Theory of Sir Wm. Thomson.

Dynamical Theory of the Electro-motive Force of the Battery.—In two very important papers published in the *Philosophical Magazine* for 1851, Sir William Thomson laid the foundations of the Dynamical Theory of Electrolysis, one of the objects of which, to use very nearly his own words, is to investigate for any circuit, the relation between the electro-motive force, the electro-chemical equivalents of the substances operated on, and the dynamical equivalent of the chemical effect produced in the consumption of a given amount of the materials, and by means of this relation to determine in absolute measure from experimental data the electro-motive force of a single cell of Daniell's battery, and the electro-motive force required for the electrolysis of water.

Thomson's law.

The relation sought for is found as follows. Let E be the electro-motive force[14] of the battery. Then, by the definition of electro-motive force, E is the whole work done in the circuit by a unit current during a unit of time. This work may appear as heat developed in the conductors or at the junctions according to the laws of Joule and Peltier, as the intrinsic energy of liberated or deposited ions, as work done by electro-magnetic forces, as "local heat" in the battery (see below, p. 85), or otherwise. Let e be the electro-chemical equivalent of any one of the elements which take part in the chemical action from which the energy of the current is derived, *i.e.*, the number of grammes of that element which enter into the chemical action during the passage of unit current for a second; and let θ be the thermal equivalent of that amount of chemical action in the battery into which exactly a gramme of the element in question would enter,—in other words, the amount of heat that would be developed were the whole energy of the amount of chemical action just indicated spent in heat. Then it is obvious that the energy of the chemical action that takes place in the battery during the passage of unit current for a unit of time is $Je\theta$, where J is Joule's equivalent. Hence, by the principle of conservation, we must have

$$E = Je\theta;$$

or, in words, *the electro-motive force of any electro-chemical apparatus is, in absolute measure, equal to the dynamical equivalent of the chemical action that takes place during the passage of unit current for a unit of time.*

The value of J is known, being 4156×10^4 in absolute units. The value of e has been found by various experimenters (see below, p. 97), the most accurate result being probably that deduced from the experiments of Kohlrausch, viz. $e = \cdot 003411$ for zinc.

[14] All our quantities are measured, of course, in C. G. S. absolute units.

Calculation from heat developed in the circuit.

We may find θ by direct calorimetric experiments on the heat developed in the circuit. In this way Joule found for the thermal equivalent of the chemical action of a Daniell's cell during the solution of 65 grammes of zinc 47670 (grm. deg. C.), and Raoult,[1] by a somewhat similar process, obtained the number 47800. These give for the heat equivalent of the chemical action during the solution of 1 grm. zinc 733 and 735 respectively. Substituting these values in our formula, we get for the electro-motive force of Daniell's cell in absolute C. G. S. units $1\cdot039 \times 10^8$ or $1\cdot042 \times 10^8$.

Calculation from chemical data.

But we may proceed in a totally different way to find the value of θ. Direct observations have been made on the heat evolved in a great variety of chemical actions, and from these experiments we can calculate, with a considerable degree of accuracy, the value of θ, and thus deduce the electro-motive force of a battery from purely chemical data. This method of procedure must of course be adopted if we wish to test the dynamical theory. Now, neglecting refinements concerning the state in which the copper is deposited, the state of concentration of the solution, etc., the chemical action in a Daniell's cell may be stated to be the removal of the Cu from $CuSo_4$ in solution, and the substitution of Zn in its place. Now, Favre and Silbermann have found for the heat developed in this chemical action 714 (grm. deg. C.) per grm. of zinc. This will give, by the above formula, for the electro-motive force of Daniell's element $1\cdot012 \times 10^8$. The chemical action might also be stated as the combination of zinc with oxygen, and the solution of the zinc oxide thus formed in sulphuric acid, the separation of copper oxide from sulphuric acid, and of the copper from the oxygen. The quantity of heat evolved in the first two actions per grm. of zinc is, according to Andrews, $1301 + 369 = 1670$ (grm. deg. C.), and that absorbed in the last two actions $588 + 293 = 881$. Hence $\theta = 789$; this gives $1\cdot118 \times 10^8$. Professor G. C. Foster[2] has calculated from Julius Thomsen's experiments values 805, 1387, and 617 of θ for the cells of Daniell, Grove, and Smee respectively; the values of the electro-motive forces corresponding to these are $1\cdot141 \times 10^8$, $1\cdot966 \times 10^8$, and $\cdot875 \times 10^8$. These results are in fair agreement with the different values of the electro-motive force obtained from direct experiment.

Limit of electro-motive force for electrolysis.

It follows from Thomson's theory that a certain minimum electro-motive force is necessary to decompose water; and he calculated from the data of Joule that this minimum was 1·318 times the electro-motive force of a Daniell's cell. Favre and Silbermann found for the heat developed in the formation of H_2O 68920, from which we conclude that the minimum electro-motive force required to electrolyze water is $68920 \div 47800$, *i.e.*, 1·44 times that of a Daniell's cell.[3]

Local heat.

Development of Heat at the Electrodes.—In a remarkable paper,[4] which we have already quoted, Joule investigated directly the disturbing effect of the electrodes on the heat developed in an electrolyte.

Joule's method.

His method was as follows:—A coil of wire whose resistance was known in terms of a certain standard was inserted in the circuit of six Daniell's elements, and the heat evolved in it carefully measured by immersing it in a calorimeter. The resistance of the rest of the circuit, including that of the battery, was found by interpolating a known resistance in the circuit and observing, by means of a tangent galvanometer, the ratio in which the current was reduced. (The assumption is here made that the electro-motive force of a Daniell's cell is constant for different currents.) Knowing the heat evolved in a part of the circuit of known resistance, and knowing the resistance of the whole circuit, the heat evolved according to Joule's law in the whole circuit during the oxidation of 65 grammes of zinc can be calculated from the indications of the tangent galvanometer previously compared with a voltameter. Hence the thermal equivalent Θ of the work done by the electro-motive force of a Daniell's cell during the solution of 65 grm. zinc can be found. The value of Θ arrived at by Joule in this way is 47670 (grm. deg. C.).

Electrolytic cells of various construction were then inserted into the circuit. The electro-motive force resisting the passage of the current through the cells was found by taking the number of battery cells just sufficient to produce electrolysis, observing the current, then increasing the number of cells by one and observing the current again. If i be the current in the first case, corrected to bring it to the value it would have had if the resistance of the whole circuit had been the same as in the second case, and j the current in the second case, then, E being the number of battery cells used in the first case, the electro-motive force Z opposing the current is given by

$$Z = E - \frac{i}{i - j},$$

the unit being the electro-motive force of a Daniell's cell. Z being known and assumed constant for different currents within certain limits, the resistance of the whole circuit, electrolyte included, can be found by Ohm's method as above. The amount of heat H which ought to be developed in the electrolyte by Joule's law can then be calculated. The amount of heat H′ actually developed was observed. It was found that H′ is in general greater than H, the difference per electrolysis of 65 grm. zinc with various electrodes is shown in the following table:—

Joule's Results.

Electrode.		Z	H′−H	L	Z − L
+	−				
Pt	Amg. Zn	2·81	66300	1·39	1·42
Pt	Pt	2·47	53000	1·11	1·36
Ag[1]	Ag[1]	1·75	16400	·34	1·40
Pt[1]	Pt[1]	1·90	28800	·60	1·29
Pt[1]	Pt[1]	1·90	26700	·56	1·34

[1] Platinized.

The electrolyte in all these cases was dil. H_2SO_4, excepting the last case, where it was a solution of potash of sp. g. 1·063. In all the cases the chemical process is finally the same or very nearly so, viz., the freeing of the elements of water, hydrogen and oxygen, in the ordinary gaseous[5] state, and the transference of a certain quantity of H_2SO_4 from the negative to the positive electrode, or of alkali in the opposite direction. Yet the values of $H' - H$ (which we may call the local heat) are very different. It will be seen, however, that the values of $H' - H$ and Z rise and fall together; and, if we calculate the electro-motive forces (L) corresponding to the values of $H' - H$, by dividing by 47670, which was found for the thermal equivalent of the electro-motive force of a Daniell's cell, and subtract the values of L thus found from Z, we get results which are not far from constant.

Local heat and residual electro-motive force.

The mean of the values of $Z - L$ is 1·36, the thermal equivalent of which is 64800, which is not very different from 68900, the heat evolved in the combination of 2 grm. of H with 16 grm. of O to form water. It appears, therefore, that the local heat corresponds to the excess of the electro-motive force of polarization over the electro-motive force requisite to separate water into its component gases. In other words, the work done by the current against this residual electro-motive force is accounted for by the local heat $H' - H$ developed in the cell (see Joule's statement above, p. 84). A glance at the column L in the above table shows that this residual electro-motive force depends greatly on the nature of the electrodes. Thus when the positive and negative electrodes are plates of platinum and zinc respectively the residual electro-motive force is 1·39, whereas with platinized silver plates it is only ·34. Local heat and the corresponding electro-motive force play a very important part in the working of batteries. Owing to this cause there is an evolution of heat in the cell itself which varies with the strength of the current, and uses up a certain definite fraction of the energy furnished by the solution of the zinc. By sufficiently increasing the external resistance, the amount of heat developed *in the cell* according to the law $JH = RI^2$ can be made as small a fraction as we please of the *whole* heat thus developed; but the amount of local heat generated in the cell during the solution of 65 grm. zinc is not greatly altered in this way, at least not in a cell of Daniell, or in any other of the so-called constant batteries. Did our space permit we might quote a great variety of experimental results to illustrate the principles we have been discussing. Most of these investigations are due to the French physicists Favre and Silbermann, whose researches have greatly advanced this department of the science of energy.

---

[1] Wiedemann, Bd. ii. 2, § 1118.

[2] Everett, *Illustrations of C. G. S. System of Units*, p. 77. No reference to the source is given.

[3] Verdet (*Théorie Méc. de la Chaleur*, tom. ii. p. 207) states that Favre was the first to point this out, but gives no citation. It seems unlikely that Favre considered the matter so early as 1851. (See Violle's bibliography at the end of Verdet's volume.)

[4] *Mem. Lit. and Phil. Soc. Manchester*, ser. 2, vol. vii., 1843. This paper seems to have been in a great measure lost sight of. In his earlier papers (*Pogg. Ann.*, ciii. § 504, 1858) Bosscha says he had not seen it. Poggendorff, in a note, p. 504, appreciates it in a manner which appears to us unjust. This may have arisen from misunderstanding of Joule's terminology, however. Verdet (*Chaleur*, tom. ii. p. 204) does not seem to have been acquainted with it. It is mentioned in the bibliography by M. J. Violle, however, under 1846, which is the date of the volume of the *Memoirs* in which it was published. The paper was actually read Jan., 1843.

[5] The amount of oxygen that finally escapes in the active state as ozone is very small.

Favre and Silbermann. Bosscha.

Very copious extracts from the memoirs of these and other physicists who have worked in this department will be found in Wiedemann, Bd. ii. 2, §§ 1121 *sqq.* The reader who desires to follow this interesting subject to the sources will find his labor much lightened by referring to M. J. Violle's excellent bibliography of the mechanical theory of heat, appended to the second volume of Verdet's *Théorie Mécanique de la Chaleur.* Much has been done for the theory of the subject by a series of papers on the mechanical theory of electrolysis by Bosscha,[1] in which the somewhat complicated phenomena involved are analyzed in a remarkably clear and able way. Any reader who desires to know what has been done in this department will do well to consult these papers. We quote the following as an example of Favre and Silbermann's results and of the calculations of Bosscha.

The heat evolved in a cell of Smee[2] and in platinum wires of different lengths through which it was circuited was measured with the following result:—

Heat in cell.	Heat in wire.	Length of wire.	Heat in cell calc.
13127	4965	25 mm.	13523
11690	6557	50 "	11788
10439	7746	100 "	10188
8992	90[illegible]0	200 "	9048

The heat in each case is that evolved during the liberation of 1 grm. of hydrogen in the cell. If we assume that the whole heat in the cell and in the wire is generated according to Joule's law, and calculate on this hypothesis the resistance of the cell in mm. of the wire, we should get values varying from 66 to 200 mm. If, however, we assume, in accordance with the principles explained above, that a constant fraction of the whole energy per grm. of liberated hydrogen appears as local heat in the cell, Q denoting the whole heat which appears in the cell, L the local heat, H the heat in the wire, R the resistance of the cell, S that of the wire, we have

$$\frac{Q-L}{H}=\frac{R}{S};$$

and it is found that on making $R = 32{\cdot}3$ and $L = 7589$, this formula will represent the results of experiment very fairly. The last column in the above table gives the value of Q thus calculated. In general so good an agreement is not to be expected, because L may and does vary with the strength of the current.

Theories of residual electro-motive force.

Thus far we have been dealing with the direct results of experiment, but when we inquire into the reason for the existence of this residual electro-motive force and of the local development of heat corresponding to it, and, in particular, when we ask why the effect is so much greater with some metals than with others, the answers become less satisfactory. We meet, in fact, with considerable divergence of opinion.

Joule's view was that the effect is due to the affinity of the metal of the electrode for oxygen. This is endorsed to a certain extent by Sir William Thomson, who puts the matter thus:[3]—"In a pair consisting of zinc and tin the electromotive force has been found by Poggendorff to be only about half that of a pair consisting of zinc and copper, and consequently less than half that of a single cell of Smee's. There is therefore an immense loss of mechanical effect in the external working of a battery composed of such elements, which *must* be compensated by heat produced within the cells. I believe, with Joule, that this compensating heat is produced at the surface of the tin in consequence of hydrogen being forced to bubble up from it, instead of the metal itself being allowed to combine with the oxygen of the water in contact with it. A most curious result of the theory of chemical resistance is that, in experiments (such as those of Faraday, *Exp. Res.*, 1027, 1028) in which an electric current passing through a trough containing sulphuric acid is made to traverse a diaphragm of an oxidizable metal (zinc or tin), dissolving it on one side and evolving bubbles of hydrogen on the other, part (if not all) of the heat of combination will be evolved, not on the side on which the metal is being eaten away, but on the side at which the bubbles of hydrogen appear. It will be interesting to verify this conclusion by comparing the quantities of heat evolved in two equal and similar electrolytic cells in the same circuit, each with zinc for negative electrode, and one with zinc the other with platinum or platinized silver for the positive electrode."[4]

Bosscha dissents from the theory of "chemical resistance" thus expounded, and advances a different explanation. According to him, the local heat arises from the energy lost by the liberated ions in passing from the *active* to the ordinary state. We know that the hydrogen which is being liberated at the surface of an electrode can effect reductions which hydrogen in the ordinary state cannot accomplish; it is liberated in fact in a state of greater intrinsic energy than usual. It is this excess of intrinsic energy which appears as local heat, and gives rise to the residual electro-motive force in electrolysis. Different metals possess in very different degrees the power of reducing active hydrogen to the ordinary state; and therefore the proportion of hydrogen which gets away from the electrode in the active state differs according to circumstances. Bosscha's theory is that it is the intrinsic energy thus *carried away from the electrode* that appears as local heat. Similar remarks apply of course to oxygen, the active form of the gas being probably ozone. As a verification of the theory, the fact is cited that at the surface of a plate of carbon, which possesses in an eminent degree the power of reducing ozone to the ordinary state, the residual electro-motive force and local heat are very small. At all events the theory of "chemical resistance" is held to be inadequate to explain the facts; for calculating from some results of his own, combined with those of Lenz and Saweljew, he finds for the residual electro-motive force at electrodes of

Pt	Fe	Cu	Sn	Hg	Zn
·45	·49	·64	·86	1·20	1·20;

from which it appears that the order of magnitude of the electro-motive forces is not that of the affinities of the metals for oxygen.

Measurement of chemical affinity. Joule.

Electrical Measure of Chemical Affinity.—In a paper[5] sent to the French Academy to compete for a prize offered for the best essay on the heat of chemical combination, Joule elaborates an ingenious method for measuring chemical affinity. By direct observation it is ascertained how much heat is developed in a given time in a certain standard coil of wire, when it is traversed by a current whose strength is measured by means of a tangent galvanometer. Then three readings of the tangent galvanometer are taken—first, when the galvanometer alone is in circuit with the battery, secondly, when the standard coil is also inserted, thirdly, when an electrolytic cell is inserted instead of the coil. The amount of the ions liberated and the heat evolved in the cell during a given time is also observed in the last case. If A, B, C be the readings of the galvanometer in the three cases, and if x be the *resistance of a metallic wire capable of retarding the current equally with the electrolytic cell,*[6] then we easily get, taking the resistance of the standard coil as unity,

$$x=\frac{(A-C)B}{(A-B)C}.$$

---

[1] *Pogg. Ann.*, ci., ciii., cv., cviii. 1857, etc.

[2] Amalgamated zinc and platinized copper.

[3] *Phil. Mag.*, 1851 (2), p. 556.

[4] The effect here predicted was afterwards observed by Thomson himself, *Rep. Brit. Assoc.*, 1852, and later still by Bosscha, *Pogg. Ann.* ciii. p. 517.

[5] Noticed in the *Comptes Rendus*, Feb., 1846, and published at length in *Phil. Mag.*, 1852.

[6] Notice that it is not said that x is equal to the resistance of the electrolyte. Bosscha in the papers we have quoted, either from not having seen the paper we are now analyzing, or through a misunderstanding, accuses Joule of error here. The reasoning (*Pogg. Ann.*, ci. p. 540) which he seems to quote from Joule is not to be found in this or in any other of Joule's papers that we know of. Polarization *is* taken into account by Joule (see *Phil. Mag.*, 1852 (1), p. 485). The criticisms of Verdet, who seems to follow Bosscha, are equally groundless (*Théorie Mécanique de la Chaleur*, t. ii. p. 204).

Now if the resistance x were put in the place of the electrolytic cell, the current would be the same: hence by Faraday's law the amount of chemical energy absorbed in the battery would be the same. Also the heat evolved in the rest of the circuit, excluding x, would be the same. It follows, therefore, that the heat H *which would be* evolved in x is the equivalent of the whole energy given out in the electrolytic cell. If therefore we subtract from H the heat K which actually appears in the cell, the remainder $H - K$ is the heat equivalent of the intrinsic energy of the liberated ions; and, provided they appear finally in the "ordinary"[1] condition, $H - K$ is the heat which would be developed when they are allowed to combine.

In this way Joule found for the heat evolved in the combustion of 1 grm. of copper, zinc, and hydrogen respectively 594, 1185, 33553.

Galvanic Batteries.—It would be inconsistent with our general plan to attempt an exhaustive discussion of all the different electro-motors which depend for their energy on chemical action. Wiedemann's *Galvanismus*, or books on telegraphy and other arts in which electricity is applied to technical purposes, may be consulted by the reader who wishes for fuller information. A brief discussion of some typical batteries will, however, be useful, were it only to illustrate the principles we have just been laying down.

One-fluid batteries.

All the earlier batteries were one-fluid batteries. The plates usually consisted of zinc and copper, and the exciting fluid was in general sulphuric acid. Various improvements were made by Cruickshank, Wollaston, Hare, and others, in the way of rendering the battery more compact, and of reducing its internal resistance by enlarging the plates. Hare carried the last-mentioned improvement to great lengths; by winding up together in a spiral form sheets of copper and zinc, insulated from each other by pieces of wood, plates of 40 or more square feet surface were obtained. In this way the internal resistance was very much reduced, and powerful heating effects could be obtained. When small internal resistance is no object, the cells of the battery may be filled with sand or sawdust, moistened with the dilute acid. In this form the battery is more portable.

Local action and polarization.

There are two capital defects to which all one-fluid batteries are more or less subject. In the first place, whether there is or is not external metallic connection between the plates, a certain amount of chemical action goes on at the surface of the zinc, which consumes the metal without aiding in the production of the current. To this is given the name of local action. It is supposed to arise from inequalities in the zinc, on account of which one portion of the metal is electropositive to a neighboring portion; hence local currents arise causing an evolution of hydrogen at some places and solution of the zinc at others. In the second place, when the battery is in action, there is always an evolution of hydrogen at the copper or electro-negative plate of the cell, a certain amount of which adheres to the plate and causes a strong electro-motive force of polarization. The first of these evils is remedied to a great extent by amalgamating the zinc plate. We thus reduce the surface metal to a fluid condition everywhere, and thereby eliminate differences of hardness and softness, crystalline structure, and so on. The oldest method was to use zinc amalgam for the electronegative metal; but it is now universally the custom to amalgamate the surface of the zinc plates simply, which may be done by rubbing them with mercury under dilute sulphuric acid. No such effective cure has been found for the hydrogen polarization. Smee introduced the plan of using instead of the copper plates thin leaves of platinum or silver foil, which are platinized by the process already described (p. 82). This, in accordance with what we have already seen, diminishes the polarization.[2] A similar result is obtained by using for the electro-negative plate cast iron or graphite; the action of the latter is much improved by steeping it in nitric acid.

Oxidizing agents.

This last fact introduces us to a new principle for improving the action of batteries, viz., the use of an oxidizing agent to get rid of the hydrogen polarization. When the plates of a Smee's battery have been exposed to the air for some time, it is always found that the current is much more energetic than usual just after the first immersion. The improvement is of course only temporary, for the stock of oxygen is soon exhausted, and on raising the plates and dipping them again *immediately*, the phenomenon does not appear. Davy found that dilute nitric acid acted better than dilute sulphuric acid as an exciting fluid, and the cause of this is the action of the HNO_3 on the hydrogen evolved at the copper plate. Good instances of this kind of action are furnished by the bichromate-battery of Bunsen and the Léclanché cell, which occupy a sort of middle position between one- and two-fluid batteries.

The bichromate cell consists of an amalgamated zinc plate, usually suspended between two parallel carbon plates, so that it can be raised or depressed at pleasure. The bichromate solution is made, according to Bunsen, by mixing 605 parts of water with 61·8 of potassium bichromate and 116 of sulphuric acid. The electro-motive force of the bichromate cell is very great to start with (more than twice that of a Daniell's cell), but it falls very quickly when the external resistance is small. The cell recovers pretty quickly however, and may be used with advantage where powerful currents of short duration are often wanted. In the cell of Léclanché the electro-negative metal is replaced by a porous vessel filled with carbon and pounded peroxide of manganese. The exciting liquid used is chloride of ammonium. Chloride of zinc is formed at the zinc plate, and ammonia and hydrogen appear at the negative plate; the latter reduces the MnO_2, so that H_2O and Mn_2O_3 are formed, while the ammonia is partly dissolved and partly escapes. This element is tolerably constant if it be not used to produce very strong currents, but its great merit consists in being very *permanent;* for it will keep in condition for months with very little attention, furnishing a current now and then when wanted; hence its extensive use in working electric bells, railway signals, and so on,

Two-fluid batteries.

It cannot be said that any of the batteries we have described, or in fact any battery on the one-fluid system, satisfies to any great extent the requirements of a constant electro-motor, which are to give the same electro-motive force whatever the external resistance, and to preserve that electro-motive force unaltered for a considerable time. The best solution of the problem to construct a constant battery is the two-fluid principle invented by Daniell; and on the whole, the best application of that principle is the cell originally given by him. This consists essentially of a plate of copper immersed in a saturated solution of copper sulphate, and a plate of zinc immersed in dilute sulphuric acid or zinc sulphate, the copper solution being separated from the other by some kind of diaphragm, usually a porous vessel of unglazed earthenware. The chemical action consists of the solution of the zinc plate to form zinc sulphate, the formation of zinc sulphate at the diaphragm and the deposition of copper at the copper plate; thus:—

$$\mathrm{Zn}\quad \overline{\mathrm{SO_4}}\mathrm{Zn}\quad \mathrm{SO_4Zn} \mid \mathrm{SO_4C\overline{u}}\quad \overline{\mathrm{SO_4Cu}}\quad \mathrm{Cu}$$

gives $$\overline{\mathrm{ZnSO_4}}\quad \mathrm{ZnS\overline{O_4}}\quad \mathrm{Zn} \mid \overline{\mathrm{So_4}}\quad \overline{\mathrm{CuSO_4}}\quad \mathrm{Cu\overline{Cu}}.$$

The evolution of hydrogen and the polarization arising therefrom are thus avoided.

Daniell's element.

A very common arrangement of this cell is a porous vessel, containing the copper plate and the sulphate of copper, with a small store of large crystals to keep the solution saturated. This vessel is dipped into another nearly filled with a semi-saturated solution of zinc sulphate, in which is placed the zinc plate. With a little care to keep the cell clean by occasionally removing some of the zinc solution and diluting to prevent incrustation, to feed the copper solution, so that it may not get weak and deposit hydrogen instead of copper on the copper plate, to keep down the level of the copper solution, which is constantly rising by osmose (see art. ELECTROLYSIS), and a few other obvious precautions, a battery of Daniell's cells will furnish a very nearly constant current, and keep in order for a long time. It is necessary to keep the current going, otherwise the solutions diffuse through the porous vessel, the result of which is a deposit of copper on the zinc, and other mischiefs, which stop the action of the cell altogether.

Daniell's element has been constructed in a great variety of forms, to suit various purposes. The sawdust Daniell, invented by Sir Wm. Thomson[3] (1858), is very convenient when portability is desired. In this form the copper plate, soldered to a gutta-percha covered wire, is placed at the bottom of a glass vessel and covered with crystals of copper sulphate; over these wet sawdust is sprinkled, and then more sawdust, moistened with a solution of sulphate of zinc, upon which is laid the zinc plate. The cell of Minotto is very similar to this.

---

[1] This word is left purposely a little vague, and is used to avoid a long discussion of points which need not be raised here.

[2] Fleeming Jenkin gives ·47 volt as the available electro-motive force of Smee's cell. The electro-motive force when the circuit is broken is much greater. See above, p. 84.

[3] Jenkin, *Electricity and Magnetism*, p. 224.

In these batteries the sawdust takes the place of the porous diaphragm, and retards the interdiffusion of the fluids. In another class of batteries, of which the element of Meidinger may be taken as the type, the diaphragm is dispensed with altogether, and the action of gravity alone retards the diffusion. In Meidinger's cell the zinc is formed into a ring, whith fits the upper part of a glass beaker filled with zinc sulphate. At the bottom of this beaker is placed a smaller beaker, in which stands a ring of copper, with a properly insulated connecting wire. The mouth of the beaker is closed by a lid, with a hole in the centre, through which passes the long tapering neck of a glass balloon, which is filled with crystals of copper sulphate; the narrow end of this neck dips into the small beaker, the copper sulphate runs slowly out, and being specifically heavier than the zinc sulphate, it collects at the bottom about the copper ring.

Yet another form of Daniell's element is the tray cell of Sir William Thomson, which consists of a large wooden tray lined with lead, the bottom of which is covered with copper by electrotyping. The zinc is made like a grating, to allow the gas to escape, and is enveloped in a piece of parchment paper bent into a tray-shape, the whole resting on little pieces of wood placed on the leaden bottom of the outer tray. Sulphate of copper is fed in at the edge of the tray, and sulphate of zinc is poured into the parchment. The zincs in these elements are some 40 centimetres square, so that the internal resistance is as low as 0·2 ohm.

Grove's element.

One of the best known in this country, and perhaps the most used of all the two fluid cells, is the element of Grove. This differs from Daniell's element in having nitric acid with a platinum electrode in the porous cell, instead of the copper solution and the copper electrode of Daniell's element. The hydrogen evolved at the platinum is oxidized by the nitric acid, and the polarization thus avoided. The nitrous fumes given off by the chemical action are very disagreeable, and also very poisonous, so that it is advisable to place the battery outside the experimenting room or in a suitable draught chamber. The electro-motive force of Grove's cell is a good deal higher than that of Daniell's, and its internal resistance is very much less, ·25 ohm being easily attained with a cell of moderate dimensions. On this account the cell is much used for working induction coils, generating the electric light, and so on, notwithstanding that it is troublesome to fit up, and must be renewed every day.

Cells of Bunsen, etc.

In Bunsen's element the platinum foils of Grove are replaced by carbon. The prime cost of the battery is thus considerably reduced, the more so now that carbons for the purpose have become articles of commerce. The electro-motive force of the element thus altered is as great as, or with good carbons even greater than, in Grove's original form; but the internal resistance is greater. There is a difficulty sometimes in obtaining good connection with the carbons, and trouble arises from their fouling; but the fact that this cell is a universal favorite in Germany proves its practical utility. It is comparatively little used in this country.

In the cell of Marié Davy, which is, or was, much used for telegraphic purposes in France, the copper solution and copper plate of Daniell are replaced by a watery paste of proto-sulphate of mercury, into which is inserted a carbon electrode. The electro-motive force of this cell is said to be about 1·5 volts,[1] and its internal resistance to be greater than that of Daniell's cell.

Besides these, various bichromate elements of merit might be described; but we have dwelt long enough on this subject already.

The following table of Latimer Clark's, quoted by Maxwell, will give the reader an idea of the relations as to electro-motive force of the commoner elements:

Daniell......	$H_2SO_4 + 4Aq$	$CuSO_4$	1·079
Do.	$H_2SO_4 + 12Aq$	$CuSO_4$	0·978
Do.	$H_2SO_4 + 12Aq$	$Cu(NO_3)_2$	1·000
Bunsen	$H_2SO_4 + 12Aq$	HNO_3	1·964
Do.	$H_2SO_4 + 12Aq$	HNO_3(sp.g. 1·38)	1·888
Grove........	$H_2SO_4 + 4Aq$	HNO_3	1·956

The electro-motive force is stated in volts, and the solutions in the third column are concentrated, unless it is otherwise stated.

Seebeck's discovery.

Thermo-electricity.—We have already alluded to the law of Volta, according to which there can be no resultant electro-motive force in a circuit composed solely of different metals; and it will be remembered that we added the condition that all the junctions must be at the same temperature. Seebeck was the first to discover[2] that this law is subject to exception when the junctions are not all at the same temperature. If we form a circuit with an iron wire and a copper wire, and raise the temperature of one of the junctions a little above that of the other, a current flows round the circuit, passing from copper to iron over the hotter junction; similarly, if we solder together a piece of bismuth and a piece of antimony, and connect the free ends with the copper wires of a galvanometer, then when the junction of the bismuth and antimony is heated the galvanometer indicates a current passing from bismuth to antimony over the hot junction. It will be perceived that the second of our two illustrative instances is more complicated than the first, inasmuch as three metals enter into the circuit instead of two. Nevertheless the experimental result is not altered by the intervention of the copper wire (abstraction being made of its resistance), provided the temperatures of the points where it joins the bismuth and antimony respectively be the same. It is easy to give a direct experimental proof of this assertion by inserting between the pieces of bismuth and antimony a piece of copper wire so that the circuit now is Bi.Cu.Sb.Cu.Bi.; if the junctions of the inserted wire with the bismuth and antimony be raised to the same temperature as the BiSb junction in our second experiment, and the junctions with the copper wire of the galvanometer be at the same lower temperature as before, the total electro-motive force in the circuit will be the same; and, provided the resistance of the circuit has not been sensibly increased by the interpolation of the copper wire, the galvanometer indication will also be the same as before. The same result is obtained however many different metals we insert between the bismuth and antimony, provided the temperatures of all the junctions be the same and equal to that of the BiSb junction in the original experiment.

The law of Volta therefore still holds if stated thus: *A series of metals whose junctions are all at the same temperature may be replaced by the two end metals of the series without altering the electro-motive force in any circuit of which the series forms a part.*

It is not unlikely that the above statement of the fundamental facts concerning thermo-electro-motive force has suggested to the reader two notions:—1st, that the phenomena may be completely explained by a *contact force* at the junctions of the metals which is a function of the temperature of the junction; and 2d, that this contact force is the true contact force of Volta.

It is perhaps as well to mention even at this early stage that the first of these notions is certainly not correct, and that the second is not admitted by some of the greatest authorities on the subject.

Thermo-electric series.

Seebeck examined the thermo-electric properties of a large number of metals, and formed a thermo-electric series, any metal in which is thermo-electrically related to any following one as bismuth (see above) is to antimony, the electro-motive force in a circuit formed of the metals being *cæteris paribus* greater the farther apart they are in the series. The following is a selection from Seebeck's series:—

Bi . Ni . Co . Pd . Pt . Cu . Mn . Hg . Pb . Sn . Au . Ag . Zn . Cd . Fe . Sb . Te .

This series has only a general interest, and is not to be regarded as in any way absolute. Seebeck himself showed the great effect that slight impurities and variations of physical condition may have on the position of a metal in the series. Some specimens of platinum for instance come between zinc and cadmium. Another instance of the same kind is afforded by iron: Joule[3] found the following order to hold —cast iron, copper, steel, smithy iron.

Thermo-electric series have been given by Hankel, Thomson, and others, but we need not reproduce them here. It may be well, however, to direct the attention of the reader to the properties of metallic sulphides and of alloys which in many cases occupy extreme positions in the thermo-electric series. Alloys present anomalies in their thermo-electric properties somewhat similar to those already noticed in our discussion of their conductivity. These properties have been much studied with a view to practical applications in the construction of thermopiles. Considerable progress has been made in this direction (see above p. 10), notwithstanding the fact that many of the alloys most distinguished for their thermo-electric power are very brittle and have a tendency to instability under the continued action of heat.[4]

Thermo-electro-motive force.

Many measurements of the electro-motive force of thermo-electric couples have been made by Matthiessen,[1] Wiedemann,[2] E. Becquerel,[3] and others, but the results are of no great value owing to the effect of impurities and the want of sufficient data to determine all the thermo-electric constants of any one couple (see below, p. 92). Numerical data, such as they are, will be found in Wiedemann, Fleeming Jenkin's *Electricity and Magnetism*, or Everett's *Illustrations of the Centremetre-gramme-second System of Units*. It will give the reader an idea of the order of the magnitudes involved to state that the electro-motive force at ordinary temperatures of a BiSb couple is somewhere about 11700 C. G. S.[4] absolute units when the difference between the temperatures of the junctions is 1° C. The corresponding number for a CuFe couple is 1600 or 1700.

Thermo-electric currents, or at least what may very likely be such, have been obtained in circuits other than purely metallic, *e. g.*, in circuits containing junctions of metals and fluids,[5] metals and melted salts,[6] fluids and fluids.[7] The phenomena in all these cases are complicated, and the results more or less doubtful; so that no useful purpose could be served by discussing the matter here. The same remark applies to the curious electrical phenomena of flames,[8] of which no proper explanation, so far as we know, has as yet been given.

Experiments of Magnus.

The experiments of Magnus[9] have shown that in a circuit composed entirely of one metal, every part of which is in the same state as to hardness and strain, no thermo-electro-motive force can exist, no matter what the variations of the section or form of the conductor or what the distribution of temperature in it may be (so long as there is neither discontinuity of form nor abrupt variation of temperature).

This statement is of great importance, as we shall see, in the theory of thermo-electricity. Its purport will be all the better understood if we dwell for a little on the three limitations which accompany it.

The great effect of the hardness or softness and crystalline or amorphous structure of a metal on its electric properties was observed by Seebeck soon after the discovery of thermo-electricity.[10] The effect of temper in wires may be shown very neatly by the following experiment due to Magnus. On a reel formed by crossing two pieces of wood are wound several turns of hard-drawn brass wire softened in a number of places adjacent to each other on the reel. The free ends of the wire being connected with a galvanometer, and the parts of the wire lying between neighboring hard and soft portions being heated, a thermo-electric current of considerable strength is obtained, whose direction is from soft parts to hard across the heated boundaries. Effects of a similar kind were obtained with silver, steel, cadmium, copper, gold, and platinum. In German silver, zinc, tin, and iron, the current went from hard to soft across the hotter boundary.

Effects of strain, etc. Sir Wm. Thomson.

Sir William Thomson made a number of experiments on the effect of strain on the electric properties of metals. The results, some of them very surprising, are contained in his Bakerian Lecture,[11] along with many other things of great importance for the student of thermo-electricity.

Two of his experiments may be described as specimens. They afford convenient lecture-room illustrations of the subject under discussion. (1.) A series of copper wires A, B, C, D, E, F, G, etc., are suspended from a horizontal peg. A and B, C and D, E and F, etc., are connected by short horizontal pieces of copper wire, all lying in the same horizontal line, and B and C, D and E, F and G, etc., are connected by a series of pieces lying in another horizontal line below the former. An arrangement is made by means of which the alternate wires A, C, E, G, can be more or less powerfully stretched, while B, D, F, etc., are comparatively free. A piece of hot glass is applied to heat either the upper or lower line of junctions. A thermo-electric current is then observed passing from the stretched to the unstretched copper across the hot junctions. This thermo-electric current increases with the traction up to the breaking point. But the most remarkable point that comes out in such experiments is that when we free the wire after powerful traction, leaving it with a permanent set, there is still a thermo-electric current; but the direction is now from the soft or unstrained towards the permanently strained parts across the hot region. (2.) Iron gives similar results, only the direction of the current is in each case opposite to that in the corresponding case for copper. The following experiment exhibits this in a very elegant manner. One end of a piece of carefully annealed iron wire is wound several times round a horizontal peg, the free end being slightly stretched by a small weight, and connected with one terminal of a galvanometer. The other end of the wire is wound a few times round one side of a rectangular wooden frame, the free end being stretched by a small weight and connected with the other terminal of the galvanometer. The parts of the wire on the peg or the part on the frame is then heated, and weights are hung to the frame. As the weight increases, the deflection of the galvanometer goes on increasing. If we stop a little short of rupture, and gradually decrease the weight, the deflection of the galvanometer gradually decreases to zero, changes sign before the weight is entirely removed, and finally remains at a considerable negative value when the wire is again free.

Le Roux, etc.

These experiments of Sir Wm. Thomson's were repeated by Le Roux. The results of the two experimenters are not very concordant. This may be due to differences in the qualities of the materials with which they worked, or to the fact that Le Roux[12] worked at higher mean temperatures than Thomson.[13]

Abrupt variations of temperature.

Le Roux also repeated the experiments of Magnus, confirming his general result, but adding the two last qualifications given above. He found, contrary to the result of Magnus, that when a lateral notch is filed in a wire and one side heated, there is in general a thermo-electric current, which is greater, up to a certain limit, the deeper the notch. He also found that when two wires of the same metal, with flat ends, are pressed together, so that one forms the continuation of the other, and the wire on one side of the junction is heated, no current is obtained; but he observed a current in all cases where there was dissymmetry,—*e. g.*, where an edge of one end was pressed on the flat surface of the other, where the wires overlapped or crossed, or where the chisel-shaped end of one wire fitted into a notch in the end of the other, and the axes of the wires were inclined, and so on.

Whether a very abrupt variation in temperature in a continuous part of a metallic wire would produce a thermo-electro-motive force is a question which possesses little physical interest, since it is impossible to realize the imagined conditions. There can be no doubt, however, that, when the two unequally heated ends of a wire composed of the same metal throughout are brought together, a thermo-electric current is in general the consequence. Such currents were, it appears, observed by Ritter[14] in 1801, when cold and hot pieces of zinc wire were brought into contact. Becquerel, Matteucci, Magnus, and others have experimented on this subject. The results obtained are, no doubt, greatly influenced by the state as to oxidation, etc., of the surfaces of the metals experimented on, as has been pointed out by Franz and Gaugain. The experimental conditions, are, in truth, very complicated, and a discussion of the matter would be out of place here.[15] We may mention, however, that, at the instance of Professor Tait, Mr. Durham[16] made experiments on the transient current which arises when the unequally heated ends of a platinum wire are brought into contact. It was found that the first swing of a galvanometer of moderately long period was proportional to the temperature difference and independent of the mean temperature through a considerable range.

Thermo-electric inversion. Cumming.

Cumming, who experimented on thermo-electricity about the same time as Seebeck, and apparently independently, discovered the remarkable fact that the thermo-electric order of the metals is not the same for high temperatures as for low. He found that, when the temperature of the hot junction in a circuit of iron and copper, or iron and gold, is gradually raised, the electro-motive force increases more and more slowly, reaches a maximum at a certain temperature T, then decreases to zero, and finally changes its direction. The higher the temperature of the colder junction, so long as it is less than T, the sooner the reversal of the electro-motive force is obtained. If the temperature of the hot junction be $T+\tau$, where τ is small, then the reversal of the electro-motive force takes place when the temperature of the colder junction is $T-\tau$. If both junctions, A and B, be at the temperature T, then *either heating or cooling* A will cause a current in the same direction round the circuit, and *either heating or cooling* B will cause a current in the opposite direction.

The reversal of the current may be shown very conveniently in the manner recommended by Sir Wm. Thomson.[1]

A circuit is formed by soldering an iron wire to the copper terminal wires of a galvanometer. If one junction be at the temperature of the room and the other at 300° C. or thereby, a current flows from *copper to iron* across the hotter junction; but, if we raise the temperature of both junctions over 300° C., one being still a little hotter than the other (which can be managed by keeping both in a lamp flame, one in a slightly hotter place than the other), then the current will flow from iron to copper across the hot junction. If both junctions be allowed to cool, the *difference* between their temperatures remaining the same, the current will decrease, becoming zero when the mean temperature of the two junctions is about 280° C.; and on still further lowering the mean temperature, it will set again in the opposite direction, *i.e.*, from copper to iron across the hot junction. The fundamental facts of thermo-electric inversion were confirmed by Becquerel,[2] Hankel,[3] Svanberg,[4] etc.; but the matter rested there till it was taken up[5] by Sir Wm. Thomson[6] in the course of his classical researches on the applications of the laws of thermo-dynamics to physical problems.

Application of laws of thermo-dynamics. Sir W. Thomson.

The application of the first law of thermo-dynamics leads to no difficulty; and it indicates that the heat absorbed according to Peltier's law in the ordinary case when a current passes from copper to iron across the hotter of the junctions, minus the heat evolved at the colder junction where the current passes from iron to copper, is to be looked on as a source of part at least of the energy of the thermo-electric current. If absorption or evolution of heat occur anywhere else than at the junctions, this must be taken account of in a similar manner.

The application of the second law is of a more hypothetical character. It is true that the Peltier effects, as we may for shortness call the heat absorption and evolution at the junctions, are reversible in this sense that we might suppose the thermo-electric current, whose energy arises wholly or partly from the excess of the heat absorbed at the junction A over that evolved at the junction B, used to drive an electro-magnetic engine and raise a weight; and that we might suppose the potential energy thus obtained again expended in sending, by means of an electro-magnetic machine, a current in the opposite direction round the circuit, absorbing heat at B, evolving heat at A, and thus restoring the inequality of temperature. This process, however, must always be accompanied by dissipation of energy, (1) by the evolution of heat in the circuit according to Joule's law, and (2) by conduction from the hotter towards the colder parts of the wires. The first of these effects varies as the square of the current strength, while Peltier's effect varies as the current strength simply; so that the former might be made as small a fraction of the latter as we please by sufficiently reducing the current, and thus, theoretically speaking, eliminated. The second form of dissipation could not be thus got rid of, and could only be eliminated in a circuit of infinitely small thermal but finite electric conductivity, a kind of circuit not to be realized, as we know (see above p. 48). Still it seems a reasonable hypothesis to assume that the Peltier effects, and other heat effects if any, which vary as the first power of the strength of the current, taken by themselves are subject to the second law of thermo-dynamics. Let us now further assume that all the reversible heat effects occur solely at the junctions. Let Π, Π' denote the heat (measured in dynamical equivalents) absorbed and evolved, at the hot and cold junctions respectively in a unit of time by a unit current. Let E be the electro-motive force of an electro-motor, maintaining a current I, in such a direction as to cause absorption of heat at the hot junction. Then if R be the whole resistance of the circuit, we have, by Joule's law and the first law of thermo-dynamics,

$$EI+\Pi I-\Pi' I=RI^2, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

supposing the whole of the energy of the current wasted in heat. Hence we get

$$I=\frac{E+\Pi-\Pi'}{R}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

It appears then that, owing to the excess of the absorption of heat at the hot junction over the evolution at the cold junction, there arises an electro-motive force $\Pi-\Pi'$ helping to drive the current in the direction giving heat absorption at the hot junction. We may suppose (and shall henceforth suppose) that $E=0$, and then the current will be maintained entirely by the thermo-electro-motive force.

If we now apply the second law, we get

$$\frac{\Pi I}{\theta}-\frac{\Pi' I}{\theta'}=0,$$

θ and θ' being the absolute temperatures of the hot and cold junctions. Hence

$$\frac{\Pi}{\theta}=\frac{\Pi'}{\theta'}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Prediction of Thomson effect.

or in other words, $\Pi=C\theta$, where C is a constant depending only on the nature of the metals. In accordance with this, the thermo-electro-motive force in the circuit would be $C(\theta-\theta')$; that is, it would be proportional to the difference between the temperatures of the junctions. Now this conclusion is wholly inconsistent with the existence of thermo-electric inversions. We must therefore either deny the applicability of the second law, or else seek for reversible heat effects other than those of Peltier. This line of reasoning, taken in connection with another somewhat more difficult, satisfied Sir Wm. Thomson that reversible heating effects do exist in the circuit elsewhere than at the junctions. These can only exist where the current passes from hotter to colder parts of the *same* wire or the reverse. Thomson was thus led to one of the most astonishing of all his brilliant discoveries; for he found, after a series of researches distinguished alike for patience and experimental skill, that an electric current absorbs heat in a copper conductor when it passes from cold to hot, and evolves heat in iron under similar circumstances. This phenomenon was called by its discoverer the electric convection of heat. He expressed the facts above stated by saying that positive electricity carries heat with it in an unequally heated copper conductor, and negative electricity carries heat with it in an unequally heated iron conductor. The first statement is perhaps clearer; the value of the one given by Thomson consists in the suggestion which it conveys of a valuable physical analogy with the transport of heat by a current of water in an unequally heated pipe.[7]

Experimental verification. Thomson.

If two points AB of a uniform linear conductor, in which a current I is flowing from A to B, and evolving heat, be kept at the same constant temperature, but for the electric transport of heat the temperature distribution would be symmetrical about a point of maximum temperature half way between A and B. Owing to the electric transport of heat, the maximum will be shifted towards A in iron, towards B in copper.[8] This remark contains the principle of the experiments made by Thomson to detect the new effect.

The first experiment in which the effect was satisfactorily established was made with a conductor ABCDEFG, formed of a number of strips of iron bound together at A, C, E, and G, but opened out widely at B, D, and F, to allow these parts to be thoroughly heated or cooled. At C and E small cylindrical openings allowed the bulbs of two delicate mercurial thermometers to be inserted in the heart of the bundle of strips. The part D of the conductor was kept at 100° C. by means of boiling water, and the parts B and F were kept cool by a constant stream of cold water. The current from a few cells of large surface was sent for a certain time from A to G, then for the same length of time from G to A, and so on. In this way the effects of want of symmetry were eliminated, and the result was that the excess of the temperature at E over that at C was always greatest when the current passed from G to A; whence it follows, as stated above, that a current of positive electricity evolves heat in an iron conductor when it passes from cold to hot.

Le Roux.

Le Roux[1] has made a series of interesting experiments on the Thomson effect in different metals. He found that the effect varies as the strength of the current, and gives the following numbers representing its relative magnitudes in different metals. In lead the effect is insensible.

+		−	
Sb	64	Fe	31
Cd	31	Bi	31
Zn	11	Arg	25
Ag	6	Pt	18
Cu	2	Al	0·1
		Sn	0·1

We may now apply the mathematical reasoning given above, taking into account Thomson's effect.

Equations of Thomson.

Suppose for simplicity we have a circuit of two metals only. Let the current go from A to B over the hot junction, and let the heat absorbed in passing from a point at temperature θ to a neighboring point at temperature $\theta + d\theta$ in A be $\sigma_1 d\theta$ per unit of current per unit of time; let $\sigma_2 d\theta$ be the corresponding expression for B. Then it is obvious, from the result of Magnus (see above, p. 89), that σ_1 and σ_2 can be functions of the temperature merely; they depend, of course, on the nature of the metal, but are independent of the form or magnitude of the section of the conductor. The first and second laws now give respectively

$$E = \Pi - \Pi' + \int_{\theta'}^{\theta} (\sigma_1 - \sigma_2)\, d\theta, \quad . \quad . \quad . \quad (4)$$

$$0 = \frac{\Pi}{\theta} - \frac{\Pi'}{\theta'} + \int_{\theta'}^{\theta} \frac{\sigma_1 - \sigma_2}{\theta}\, d\theta, \quad . \quad . \quad . \quad (5)$$

where E is the whole thermo-electro-motive force, and Π and Π' are the same functions of θ and θ' respectively. By differentiation we get from (5)

$$\frac{d}{d\theta}\left(\frac{\Pi}{\theta}\right) + \frac{\sigma_1 - \sigma_2}{\theta} = 0; \quad . \quad . \quad . \quad . \quad (6)$$

whence we easily get

$$\left.\begin{aligned} E &= \int_{\theta'}^{\theta} \frac{\Pi}{\theta}\, d\theta \\ \text{or} \qquad \frac{\Pi}{\theta} &= \frac{dE}{d\theta} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

The last equation enables us to determine E in terms of Π, and conversely.

When the difference between the temperatures of the junctions is very small, equal to $d\theta$ say, the thermo-electro-motive force is

$$\frac{\Pi}{\theta} d\theta. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

The coefficient $\frac{\Pi}{\theta}$ by which we must multiply the small temperature difference to get the electro-motive force is called by Thomson the thermo-electric power of the circuit. If we have a circuit of three metals, A, B, C, all at the same temperature θ, then we know that

$$\Pi_{BC} + \Pi_{CA} + \Pi_{AB} = 0,$$

whence

$$\frac{\Pi_{AB}}{\theta} = \frac{\Pi_{AC}}{\theta} - \frac{\Pi_{BC}}{\theta}, \quad . \quad . \quad . \quad . \quad . \quad (9),$$

or, in other words, the thermo-electric power of B with respect to A is equal to the difference between the thermo-electric powers of a third metal C with respect to A and B respectively.

Tait's conjecture.

Thus far we have been following Thomson. But as yet we have no indication how σ, the coefficient of the Thomson effect, depends on the temperature. Thomson himself seems (see his Bakerian Lecture, *l. c.* p. 706) to have expected that σ would turn out to be constant. Certain considerations concerning the dissipation of energy led Tait, however, to conjecture that σ is proportional to the absolute temperature. If we adopt this conjecture, Thomson's equations give us at once the values of the Peltier effect and the electro-motive force in the circuit. If $\sigma_1 = k_1\theta$, $\sigma_2 = k_2\theta$, we get from (6) and (7) successively[2]

$$\Pi = (k_1 - k_2)(\theta_{12} - \theta)\theta, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

$$E = (k_1 - k_2)(\theta - \theta')\{\theta_{12} - \tfrac{1}{2}(\theta + \theta')\}, \quad . \quad . \quad (11)$$

where θ_{12} is the neutral temperature. Also, since in a circuit of uniform temperature there are no Thomson effects, and the sum of the Peltier effects is zero, we get for any three metals

$$(k_2 - k_3)\theta_{23} + (k_3 - k_1)\theta_{31} + (k_1 - k_2)\theta_{12} = 0. \quad . \quad (12)$$

Thermo-electric diagram developed by Tait.

Taking up the idea of a thermo-electric diagram originally suggested by Thomson, Tait has shown how to represent the above results in a very elegant and simple manner. Suppose we construct a curve whose abscissa is the absolute temperature θ, and whose ordinate is the thermo-electric power of some standard metal with respect to the metal we are considering, then, from what has been shown (10), Tait's conjecture leads to the result that this curve is a straight line; and if the standard metal be lead, for which, according to Le Roux's results, the Thomson effect is zero, then the coefficient *k* of the Thomson effect is the tangent of the inclination of the representative line to the axis of abscissæ. And not only so, but it follows from formulæ (9) and (7) that if A′AN, B′BN (fig. 54) be the lines corresponding to two metals, say Cu and Fe (of which the former is above the latter in the thermo-electric series at ordinary temperatures), and if AB, A′B′ be the ordinates corresponding to θ and θ', then the electro-motive force in a circuit of the two metals whose junctions are at the temperatures θ and θ', tending to send a current from Cu to Fe across the hotter junction, is represented by the area ABB′A′. The Peltier effects at the two junctions are represented by the rectangles AB*ba* and A′B′*b′a′*, and the Thomson effects, in the Cu and Fe respectively, by AA′DC and BB′GF, or by AA′*a′a* and BB′*b′b*, which are equal to these. At N, where the lines intersect, the Peltier effect vanishes. N therefore is the neutral point; and, if the higher temperature lie beyond it, the electro-motive force must be found by taking the difference of the areas NA′B′ and NAB, and so on. All the phenomena of inversion may be studied by means of this diagram, and the reader will find it by far the best means for fixing the facts in his memory.

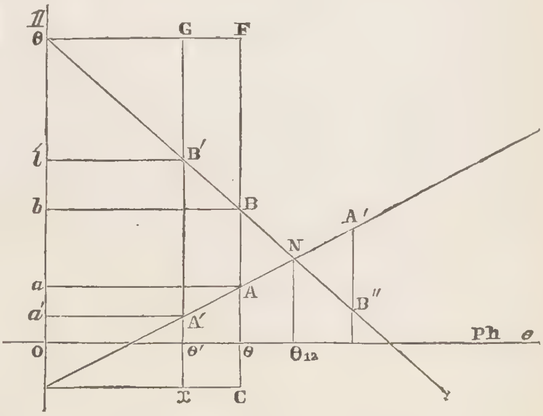

Fig. 54.

Experiments of Tait, etc.

For several years back Tait[3] and his pupils have been engaged in verifying the consequences of this conjecture; and it has been shown, first, for temperatures within the range of mercury thermometers, and latterly for temperatures considerably beyond this range, that the hypothesis accords with experience. The methods employed by Tait in his experiments at high temperatures are of great interest and importance. One of these was to construct a curve whose ordinate and abscissa are the simultaneous readings of two thermo-electric circuits whose hot and whose cold junctions are kept at common temperatures. It is a consequence of the foregoing assumption that the curve thus obtained ought to be a parabola. Very good parabolas *were* in many cases obtained. In some cases, however, the curves, so far from being parabolas, were actually curves having points of contrary flexure. This anomaly led Tait to the discovery of the astonishing fact that the Thomson effect in iron changes its sign certainly once at a temperature near low red heat, if not a second time near the melting point. It was found that the inflected curves could be represented by piecing together different parabolas. Hence the line for iron in the thermo-electric diagram is a broken line made up of two if not three straight pieces. This peculiarity of the iron line was very strikingly shown by forming circuits of iron with the alloys PtIr or PtCu. Such circuits exhibit *two or even three neutral points* (see fig. 55). Another very elegant method of verification consisted in using along with an iron wire a multiple wire of Au and Pd, the resistances of whose branches could be modified at will. It is easy enough to show that the line for the Au-Pd wire is a straight line, passing through the neutral point of Au and Pd, and such that it divides the part of an ordinate lying between the Au and Pd lines in the ratio of the respective conductivities of the Au and Pd branches. Thus, by increasing ratios of the conductivities of the Pd and Au branches from 0 up to ∞, we can make the Au-Pd line sweep through the whole of the space between Au and Pd (fig. 55), and thus explore the part of the Fe line lying in the space. We get in this way first one neutral point, then two, then one, and then none in our Fe, Au-Pd circuit.

[3] *Trans. R. S. E.*, 1873.

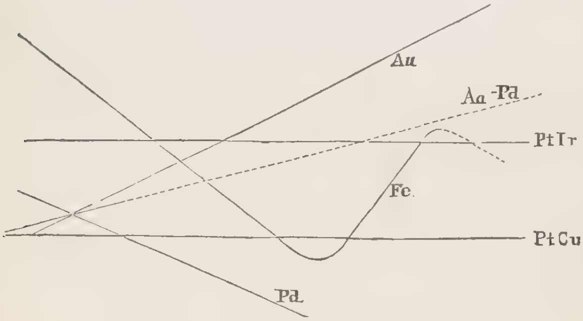

Fig. 55.

Current from Thomson effects alone.

Tait has pointed out that, by using PtIr and Fe, and keeping the hot and cold junctions at the two neutral temperatures, we get a current maintained solely by the excess of the heat absorbed in the hotter iron over that developed in the colder. The electro-motive force is represented by the area inclosed by the part of the zigzag on the Fe line cut off by the PtIr line (fig. 55). A similar case of thermo-electro-motive force without Peltier effects may be obtained with three metals, such as Fe, Cd, Cu, whose neutral points lie within reasonable limits. The electro-motive force in this case is represented by the triangle between the three lines.

Tait's results.

We subjoin a table, calculated by Professor Everett from Tait's diagram. The thermo-electric power is given in electro-magnetic (C.G.S.) units, in terms of the temperature (t) in centigrade degrees, by means of the formula $\alpha + \beta t$, where α and β have the tabulated values:—

	α	β		α	β
Fe	—1734	+4·87	Cd	— 266	— 4·29
Steel	—1139	+3·28	Zn	— 234	— 2·40
Pt Ir?	— 839	+0·00	Ag	— 214	— 1·50
Pt Ir (5 p.c. Ir)	— 662	+0·55	Au	— 283	— 1·02
Do. (10 do.)	— 596	+1·34	Cu	— 136	— 0·95
Do. (15 do.)	— 709	+0·63	Pb	+ 0	+ 0·00
Do. (15 do.)	— 577	+0·00	Sn	+ 43	— 0·55
Pt soft	+ 61	+1·10	Al	+ 77	— 0·39
Pt hard	— 260	+0·75	Pd	+ 625	+ 3·59
Pt Ni	— 544	+1·10	Ni to 175° C.	+2204	+ 5·12
Mg	— 224	+0·95	Do. 250° to 310° C.	+8449	—24·10
German silver	+1207	+5·12	Do. from 340° C.	+ 307	+ 5·12

We need scarcely warn the reader that the results in this table must not be rashly applied to any specimens of the metals taken at random. The temperature limits lie between 18° C. and 420° C.

Comparison of heat and electric measurements.

It would be extremely interesting to compare the results of absolute measurements of the Peltier effect with Tait's theory; but, unfortunately, no data that we know of are available for the purpose. It is absolutely necessary for this purpose to have heat measurements and determinations of the lines of the metals in the same specimens. The data of Edlund[1] and Le Roux are quite useless for such a purpose. One result of Le Roux's is, however, interesting. He finds for the amount of heat developed at the junction BiCu, the values 3·09 and 3·95 at 25° C. and 100° C. respectively. Since the neutral temperature of BiCu is very high, the Peltier effect ought, according to Tait's theory, to vary as the absolute temperature. The absolute temperatures corresponding to 25° C and 100° C. are 298° and 373°, and we have $3·95 \div 3·09 = 1·278$, while $373 \div 298 = 1.252$; the agreement between these numbers bears out the theory so far.[2]

Seat of electro-motive force.

General Considerations regarding the Seat of Electro-motive Force.—Before proceeding to notice the remaining cases of the origin of electro-motive force, in which the phenomena are more complicated, and the experimental conditions less understood, it may be well to call attention to a principle that appears to hold in most of the cases already examined. In most of these cases the seat of the electro-motive force appears to be at the places where energy is either taken in or given out in the circuit.[3]

It is very natural to ask ourselves what the consequences would be if we applied this principle to the voltaic circuit. It would probably be admitted by most that the energy in the voltaic circuit is taken in mainly at the surface of the electro-positive metal. This admission, taken in conjunction with the general principle above stated, leads us to the conclusion that the electromotive force resides mainly at the surface of the electropositive metal. The absorption or evolution of energy at the junction of the dissimilar metals is quite insignificant, and we should, on the same view, deny that any considerable part of the electro-motive force resides there.

This view appears to be at variance with the theory of metallic contact, as now held by Sir William Thomson and others; and the burden of explaining the experiments made by him and others on the contact force of Volta is doubtless thrown on those who adopt this view. The position of such would very likely be that there is an uneliminated source of uncertainty in all these experiments[4] (see above, p. 80). On the other hand, those who adopt the contact force of Volta at the junction of copper and zinc as the main part of the electro-motive force of Daniell's element are under the necessity of distinguishing this from the electro-motive force corresponding to the Peltier effect, which must be a distinct effect, since it is but a very small fraction of that of a Daniell's cell.

We are, however, so very ignorant of the nature of the motion which is the essence of the electric current that the very form in which we have put the question may be misleading. If this motion be in the surrounding medium, as there is great reason to believe it to be, it would not be surprising to find that speculations as to the exact locality of the electro-motive force *in the circuit* were utterly wide of the mark. The very language which we use implies a certain mode of analyzing the problem which may be altogether wrong. The only thing of which we can as yet be sure is that the mathematical equations deduced from Ohm's law and other proximate principles are in exact accordance with experiment.

Pyro-electricity.

Pyro-electricity.—Some account of this interesting subject has already been given in the Historical Sketch at the beginning of this article. It will be well, however, to state here some of the conclusions of those who have recently investigated the matter. It seems now to

[3] Maxwell, vol. i. § 249. By "being taken in," in the case of heat for instance, is meant "disappearing as heat and appearing as electrokinetic energy." In a thermo-electric circuit this transformation occurs wherever there is Peltier or Thomson effect.

[4] Maxwell, *l. c.*

Canton, Wilcke, Bergman.

be settled that it is not merely high or low temperature, *but change of temperature,* which gives rise to the electrical phenomena of pyro-electric crystals. The properties exhibited by tourmaline may be described thus. One end A of the crystal is distinguishable from the other end B by the dissymmetry of the crystalline form. A is called the *analogous* pole of the crystal, and B the *antilogous* pole. When the temperature of the crystal is increasing uniformly throughout, the analogous pole is positively electrified and the antilogous pole negatively electrified. When the temperature is decreasing uniformly throughout, the analogous pole is negative and the antilogous pole positive. This law was originally discovered by Canton,[1] but it seems to have been lost sight of again and rediscovered both by Bergman and by Wilcke in 1766. When the temperature is uniform, the positive and negative regions are symmetrically distributed about the central zone of the crystal, which is neutral. If the ends be unequally heated, this symmetry no longer obtains. It must not be forgotten that complications may arise from the crystal becoming electrical as a whole by friction, usually positive, like most other vitreous bodies.

Gaugain.

Gaugain[2] made a series of interesting experiments on the electrical properties of tourmaline, and concluded that a tourmaline whose temperature is varying may be compared to a voltaic battery of great internal resistance, consisting of an infinite number of cells, each of infinitely small electro-motive force; so that the electro-motive force is proportional to the length of the tourmaline, and its internal resistance is proportional to the section inversely and to the length directly. He also concluded that the amount of electricity furnished by a tourmaline, while its temperature varies either way between two given temperatures, is always the same.

Thomson's theory.

In order to explain the properties of the tourmaline, it has been supposed[3] that the crystal is naturally in a state of electrical polarization, like that assumed by Maxwell in a medium, under the influence of electro-motive force, or more nearly (since no sustaining force having an external origin is supposed) like that of a permanent magnet. The intensity of this polarization is supposed to be a function of the temperature. Supposing the tourmaline to remain for some time at the same temperature, a surface layer of electricity would be formed, which would completely mask the electrical polarization of the crystal, inasmuch as it would destroy all external electrical action. This neutralization would be instantly effected by running the crystal through the flame of a lamp. If, however, the temperature increase, then the polarization will, let us say, increase, so that the surface electrification no longer balances it. We shall thus get polar electrical properties of a certain kind. If the temperature decrease, the polarization will decrease, and we shall thus get polar properties of the opposite kind.

In many pyro-electric crystals there are more than one electric axis, so that we have several analogous and corresponding antilogous poles. An enumeration of the various crystals in which pyro-electric properties have been found, and a discussion of the peculiarities in their crystalline form, belong more properly to the science of Mineralogy. Much has been done in this department by Köhler,[4] Gustav Rose and Riess[5], and Hankel.[6] For some very interesting researches by Friedel see *Annales de Chimie et de Physique*, 1869.

Contact of non-conductors.

Frictional Electricity.—In accordance with the general principle laid down at the beginning of this section, we should expect to find an electro-motive force at the surface which separates two different non-conducting media, just as we have found it at the boundary of two different conducting media. The effect of such a contact force would be very different however in the former of these cases, from what we have seen it to be in the latter. In the case of non-conductors the electricity cannot leave the surface of separation, but will simply accumulate on the two sides of it, till the force arising from electrical separation is equal to the contact force. On separating the bodies, in certain cases, we may carry away with us these surface layers of electricity, and it is an obvious consequence of our principles that the electrifications of parts of the two bodies that have been in contact must be equal and opposite. While the bodies are in contact the difference of potential between the layers of electricity corresponding to very considerable surface density may be very small, just as in Volta's condensing electroscope (see above, p. 32); but when we separate the bodies work is done against the electrical attractions, and the potential increases enormously.

These hypothetical results tally very well with the electrical phenomena observed when non-conducting bodies are lightly rubbed together; and the above is nearly the explanation that most physicists of the present day would probably give (if they gave any) of what is called the "frictional generation of electricity."

All experimenters are agreed that equal quantities of positive and negative electricity appear in this case as in every other case of electrical separation; an experiment to prove the contrary would have to be very demonstrative indeed before it would now be accepted as conclusive. A single case of exception would revolutionize our fundamental ideas completely. The reader should consult on this point Faraday's *Experimental Researches,* series xi. ¶ ii.

The other consequences of our hypothesis are by no means so firmly established. One of these is that we ought to be able to arrange non-conducting bodies in a series such that any body rubbed with one below it in the series becomes positive, and rubbed by one above it negative.

Many electricians have attempted to establish such electro-motive series, but the experimental conditions (see the admirable remarks of Riess, *Reibungselectricität,* § 907) are so complicated that nothing absolute has been attained. Yet it would appear that, if we could make sure that we were always dealing with definite materials under definite surface conditions, electro-motive series could be constructed in which every different body would have a fixed position. As it is, the body bearing the same name in the lists of different experimenters was in all probability not exactly of the same material in all cases, and (we might say certainly) was not under the same surface conditions. We refer the reader to Riess (*l.c.*) for an admirable résumé of the work of different electricians in this department. Mascart has given a very interesting account of the matter (t. ii. § 834, etc.) from a more modern point of view. From these sources, together with indications in Young's *Lectures on Natural Philosophy,* the reader will be able to follow up the literature of this somewhat uninviting department of electricity.

Frictional series.

We give two instances of frictional electro-motive series which may be useful in giving the reader a *general* idea how different bodies stand.

Wilcke.

The following is Wilcke's series[7] (1758):—Glass, woollen cloth, feathers, wood, paper, shellac, white wax, ground glass, lead, sulphur, metals.

Faraday.

Faraday[8] gives—cat and bear skin, flannel, ivory, feathers, rock crystal, flint glass, cotton, linen, white silk, the hand, wood, shellac, metals (iron, copper, brass, tin, silver, and platinum), sulphur.

To which Riess adds (in order) the highly negative bodies—gutta percha, electrical paper,[9] collodion, gun cotton.

Peclet's experiments.

Considered as evidence for the contact hypothesis the experiments of Peclet seem to be important. He used an apparatus which was virtually a Nairne's machine (see below, p. 94), in which the rubber could be varied at will. His general conclusions are quite in accordance with the contact theory. He found, for instance, that for the great majority of materials the quantity of electricity generated was independent of the pressure and of the breadth[10] of the rubber, and varied as the angular velocity of the cylinder, and it even appeared to be the same for rolling friction as for sliding friction, so long as the material of the rubber was unchanged.

Contact of conductor with non-conductor.

Frictional machines.

Besides the case of two non-conductors, we might consider the case of a conductor and a non-conductor in contact. Much of what has just been said would apply to this case also, an excellent example of which is furnished by a frictional electrical machine of the ordinary construction when the cushions are well furnished with amalgam. This is the place to give a short account of these time-honored pieces of electrical apparatus. For a *history* of them we cannot do better than refer to Mascart[11] (*l.c.*) who has devoted much attention to the theory as well as the history of electrical machines in general.

A very common form of machine, called Ramsden's, is pictured in fig. 56. It consists, like all other frictional machines, essentially of three parts—(1) the rubbed or moving body, (2) the rubbers, and (3) the collectors and prime conductors. In the present instance the rubbed body is a disc of glass, which can be turned about a horizontal axis by means of a suitable handle. The efficiency of the machine depends very much on the quality of the glass of which the disc is made. According to Mascart, glass of old manufacture is superior to the more modern specimens, owing to the smaller proportion of alkali in the former; it appears, however, that the disc improves in most cases with age and use. Many other materials have been proposed to replace glass, which is somewhat costly when large discs are required. Ebonite has been tried a good deal of late, and has great advantages so far as its electrical properties are concerned; but it has the disadvantage that it warps very readily if heated incautiously, and its surface will not keep good for any length of time. Owing to decomposition under the action of light, a layer of sulphuric acid forms on the surface, after which it is very difficult to restore the electrical virtue so remarkable in the new material, although washing with hot water or immersion in a blast of steam is said to be effective in some degree.

[10] That is, the dimension of the rubber perpendicular to the axis of rotation.

[11] A few notices of the earlier machines will be found in the Historical Sketch.

The rubbers consist of two rectangular pieces of wood, hinged to supports attached to the framework of the machine, and fitted with springs and screws, so that they can be made to clip the plate with any required pressure. The rubbing surfaces are usually formed of leather, stretched as smooth and flat as possible (oiled silk is sometimes used, but it is not so durable). Before the leather cushions are fit for use, they must be carefully coated with amalgam. The amalgam most commonly used is Kienmayer's, which is a composition of two parts of mercury with one of zinc and one of tin. A great variety of different compounds of this kind have been used by different electricians, bisulphide of tin being a general favorite. The amalgam must be powdered as finely as possible, all grit being carefully removed. The cushions are then to be lightly smeared with lard, and worked together till the surface is very smooth and the greasiness almost gone; then the amalgam is to be carefully spread over them, and the surfaces again worked together till a uniform metallic surface is attained;[1] they are then ready for use. The amalgam aids the action of the machine in two ways,—first, by presenting a surface which is highly negative to glass; secondly, by allowing the negative electricity evolved by friction to flow away without hinderance from the points of contact. In order to secure the second of these advantages still more perfectly, the cushions should be carefully connected by strips of tinfoil, or otherwise, with knobs, which can be put to earth during the action of the machine.

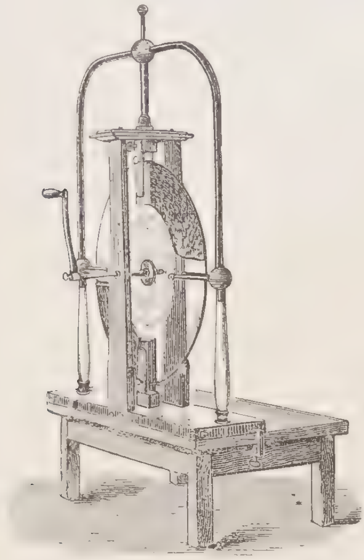

FIG. 56.—Ramsden's electrical machine.

The collectors are two stout metal forks bestriding the glass disc at the ends of a horizontal diameter. They are armed, on the sides next the glass, with rows of sharp points, which extend across the rubbed part of the disc. The prime conductor in the specimen we are describing forms a metal arch rising over the framework of the machine, and insulated from the sole by two glass pillars. Various forms are given to this part of the machine, according to the fancy or convenience of the experimenter. One important thing to be seen to is, that there be no salient points on it which might facilitate the dissipation of electricity by brush, convective, or spark discharge.

After what has been said, the action of the machine requires little explanation. The disc, electrified positively by contact with the amalgam, carries away a positive charge, whose potential rises rapidly as it leaves the cushion,—so high, in fact, that there is a tendency to discharge to the air, which is prevented by covering the excited parts of the disc by pieces of oiled silk. When the highly charged glass comes opposite the points of the collector, owing to the inductive action, negative electricity issues from the points and neutralizes the charged plate, which at this point is virtually inside a closed conductor. The result of this is that the prime conductor becomes positively charged. The neutralized parts of the disc now pass on to be rubbed by the other cushion, and so on. The electricity goes on accumulating in the prime conductor until the potential is so great that discharge by surface conduction, or by spark, takes place between the collectors and the cushion, or between the collectors and the axis.

If it is desired to obtain negative electricity from a machine with a glass disc, we have simply to connect the prime conductor to earth, insulate the cushions, and collect the electricity from them.

We have said that there is a limit to the potential to which the charge on the prime conductor can be raised. We can never get a longer spark from the machine than the length of the interval between the collector and the cushion or the axis, as the case may be. The limiting potential can, however, be increased by insulating the axis of the machine, or making the axis itself wholly or partially of insulating material, and by using only one rubber and one collector, and placing them at the extremities of a diameter. The machine of Le Roy, often called Winter's machine (fig. 57), is constructed on this pattern. We get, of course, *cæteris paribus*, only half as much electricity per revolution with a machine of this kind as with Ramsden's; but the spark is longer, in consequence of the greater insulation between the cushion (A) and the collector (B).

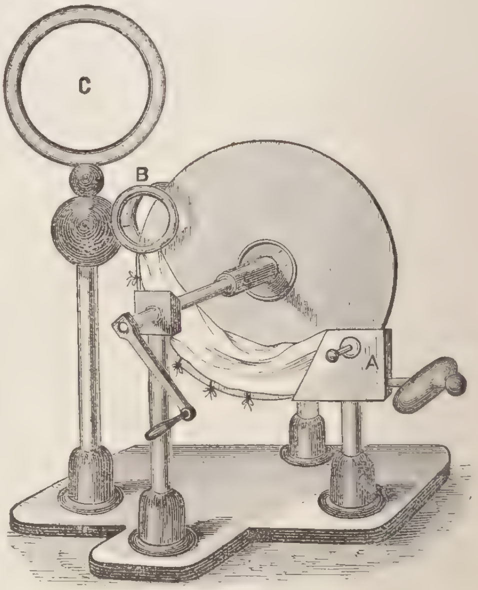

FIG. 57.—Le Roy's machine.

Nairne's machine.

The cylinder machine, also called Nairne's machine, was one of the first machines in which all the essential parts of the modern frictional machine appeared. It consists of a glass cylinder, which can be turned about a horizontal axis by a multiplying gear, or (as is now more usual) by means of a winch handle simply. The cushion is affixed to one horizontal metal cylinder, and the collector to another. It is necessary to insulate the axis in this machine, owing to its proximity to the ends of the conductors. Positive or negative electricity can be obtained with equal readiness by insulating either of the conductors, and connecting the other with the earth.

Those who desire more minute information concerning the functions of the different organs of the frictional machine, are referred to Mascart, tom. ii. § 834, etc. In the same place will be found a description of the famous machine with double plates constructed by Cuthbertson for Van Marum, and still to be seen in Teyler's Museum at Haarlem. A description of another of Van Marum's machines will be found in the article "Electricity" in the *Encyclopædia Metropolitana*. We take this opportunity of calling the scientific reader's attention to that article, which contains a great quantity of very valuable matter. Much of the work of the earlier electricians that we have been obliged to pass over in silence is fully described there.

Electric machines have also been constructed of less costly materials than glass or even vulcanite—of cloth and paper, for instance—for an account of these, see Riess, Bd. ii. §§ 936, 937.

Friction of powders, etc.

Many experiments have been made on the electrification of sifted powders. We have already, in describing Lichtenberg's figures, alluded to some cases of this kind. As a rule, either the results are very uncertain, or the conditions of the experiment very complicated, so that the experiments are, in most cases, more curious than valuable, from a scientific point of view. Such as desire it will find abundant indications of the sources of information in Riess, Bd. i. §§ 938 *sqq.*, and *Ency. Metrop.*, art. "Electricity," §§ 193 *sqq.* One case of this kind, however, was so famous in its day, that we ought to mention it. In the year 1840 a workman at Newcastle, having accidentally put one hand in the steam which was blowing off at the safety valve of a high-pressure engine boiler, while his other hand was on the lever of the valve, experienced a powerful electric shock in his arms. Armstrong investigated the matter, and was led to construct his famous hydro-electric machine. This apparatus consists simply of an insulated boiler for generating high-pressure steam, fitted with a series of nozzles, kept cool by a stream of water. The steam issues from these nozzles and impinges on a conductor armed with points for collecting the electricity. The boiler gets electrified to a high potential, and a torrent of dense sparks may be drawn from it. The machine far surpassed any ordinary electrical machine in the quantity of electricity furnished in a given time. By means of it water was decomposed, and the gases collected separately. It was reserved for Faraday to trace the exact source of the electro-motive force. He demonstrated, by a series of ingenious experiments, that the electrical action arose from the friction of the particles of water in the condensed steam against the wood of the nozzles.[1]

[1] Mascart, *l. c.*

Miscellaneous results.

Remaining Cases.—Of these the most important are atmospheric electricity,[2] which belongs properly to meteorology, animal electricity, comprehending the study of the properties of the electrical fishes, and the electric phenomena of nerve and muscle. We have already indicated the literature of the former subject, and the latter belongs, for the present at least, to physiology. Evaporation, combustion, and in fact chemical action generally, have been brought forward by some experimenters as sources of electro-motive force. About the last of all there is, of course, in one well-known case no doubt. As to the experiments generally alluded to under the other two heads—in particular those of Laplace and Lavoisier, Volta, Pouillet, and others—there has been considerable difference of opinion, and we need not occupy space here with fruitless discussion of the matter.[3] Similar remarks apply to the electrification caused by pressure, cleavage, and rupture.

Electrophorus.

Machines founded on Induction and Convection.[4]—The oldest electric machine on this principle is the electrophorus of Volta, 1775. This consists of a plate of resinous matter (now usually vulcanite) backed by a plate of metal, and a loose metal plate, which we may call the collector, fitted with an insulating handle. The vulcanite is electrified by flapping it with a cat-skin, the collector is placed upon it, uninsulated for a moment by touching it with the finger,[5] and then lifted by the insulating handle. The collector plate is then found to be charged (positively) to a high potential, and sparks of some length may be drawn from it. The explanation of the action of the electrophorus is simple enough, if we keep clearly in view the *experimental fact* that the surface electrification of a non-conductor, like vulcanite, will not pass to a metal plate in contact with it under ordinary circumstances. If the surface density of the electrification be very great, discharge to the metal may no doubt take place; and if the collector be kept for a very long time in contact with the vulcanite, it is said that it may become negatively electrified. In the normal state, however, the negative electricity of the vulcanite remains upon it, and the thin layer of air intervening between it and the collector forms the di-electric in a condenser of very great capacity, so that a quantity of electricity collects on the lower surface of the condenser very nearly equal to that on the vulcanite. The difference of potential between the plates is very small (just as in Volta's condensing electroscope, see above, p. 32). When the collector is raised it carries away the positive charge—the potential of which, owing to the decrease in the capacity of the collector, rises enormously. It is to be noticed that the potential of the charge on the vulcanite rises to a corresponding extent. This remark partly explains the remarkable fact that, when the collector is kept on the excited vulcanite, its electrification may be kept for a long time (for weeks under favorable circumstances), whereas it speedily dissipates if the vulcanite be left uncovered. According to Riess, the fact that a plate of metal laid on an excited piece of glass tends to preserve its electrification was discovered by Wilcke in 1762.

If each time we charged the collector it were discharged by contact with the interior surface of a hollow conductor A, it is obvious that we could raise A by a sufficient number of such contacts to as high a potential as we please, provided it were sufficiently well insulated. This remark brings Volta's electrophorus into the present category of electrical machines.

In the rest of the induction machines to be described the excited di-electric is dispensed with, and an electrified conductor substituted in its place.

Bennet's doubler.

The earliest apparatus that involved the principle of such machines appears to have been Bennet's doubler.[6] The principle of this apparatus may be explained thus. Let A and C be two fixed discs, and B a disc which can be brought at will within a very short distance of either A or C. Let us suppose all the plates to be equal, and let the capacities of A and C in presence of B be each equal to p, and the coefficient of induction between A and B, or C and B, be q. Let us also suppose that the plates A and C are so distant from each other that there is no mutual influence, and that p' is the capacity of one of the discs when it stands alone. A small charge Q is communicated to A, and A is insulated, and B, uninsulated, is brought up to it; the charge on B will be $-\frac{q}{p}Q$. B is now uninsulated and brought to face C, which is uninsulated; the charge on C will be $\frac{q^2}{p^2}Q$. C is now insulated and connected with A, which is always insulated. B is then brought to face A and uninsulated, so that the charge on A becomes rQ, where

$$r = \frac{p}{p+p'}\left(1+\frac{q^2}{p^2}\right).$$

A is now disconnected from C, and here the first operation ends. It is obvious that at the end of n such operations the charge on A will be r^nQ, so that the charge goes on increasing in geometrical progression. If the distance between the discs could be made infinitely small each time, then the multiplier r would be 2, and the charge would be doubled each time. Hence the name of the apparatus.

Darwin, Cavallo, Nicholson.

Darwin, Cavallo, and Nicholson[7] devised mechanism for effecting the movements which in Bennet's instrument were made by hand. Cavallo's was a reciprocating movement, but in the machines of Darwin and Nicholson the motion was continuous and rotatory. Nicholson's doubler is a very elegant instrument. A drawing of it is given by Mascart (t. ii. § 845); the specimen there represented is very like one which was found among the late Professor Willis's apparatus, and is now in the Cavendish Laboratory at Cambridge. A still more elegant machine is "Nicholson's spinning condenser," which bears a remarkable resemblance to the induction machine of Töpler.[8] A description, with a figure, will be found in the *Encyclopædia Metropolitana*, art. "Electricity," § 112.

It is obvious that if any conductor be connected with the part of any of these machines corresponding to the conductor A in the above description, and the potential of A be raised to any small positive or negative value,[9] we can by means of the machine increase the charge, and therefore the potential, up to any required amount. We have, in fact, an electric machine which may be used for all the ordinary purposes. It was not with this view, however, that these pieces of apparatus were first invented, but rather for the purpose of demonstrating small electric differences. In this they were but too successful, for it was found that it was impossible to prevent them from indicating electric differences unavoidably arising within the apparatus itself. It was this difficulty no doubt that led to their being ultimately abandoned, and for a time forgotten, although they were once in high favor. Of late, however, they have been taken up as electro-motors with great success.

Typical convecto-inductive machine.

The type of all these machines is an arrangement of the following description. A conductor or carrier C, or a series of carriers, is fastened upon the circumference of an insulating disc. At the ends of a diameter are two hollow conductors, A and B, embracing the disc on both sides, so that twice in the course of a revolution the carrier is virtually in the interior of a hollow conductor. Inside each conductor are two springs: one of these is in metallic connection with the conductor, and may be called the receiving spring; the other, called the inductor spring, is insulated from the conductor, and is connected either to earth or with the corresponding spring belonging to the other conductor. Suppose A to be at a small positive potential, and B at zero potential; starting with C in connection with the inductor spring inside A, it becomes negatively electrified and carries away its charge; it next comes in contact with the receiving spring in B, and, being now part of the interior of a hollow conductor, it parts with the whole of its charge to B; then it passes on and is charged positively at B's inductor spring; then discharges to A at A's receiving spring; and so on. The positive and negative charges are each a little increased every revolution, and the difference of potentials accordingly augmented. This is the principle of Varley's machine[1] (1860), and of Thomson's mouse mill and replenisher[2] (1867); it is virtually that of Bennet's doubler.

[9] By connecting the conductor with the positive or negative pole of a small galvanic battery, for instance.

Water-dropping machine.

Closely allied to these machines is Thomson's water-dropping potential equalizer. This consists of an insulated reservoir of water, with a long pipe, from the nozzle of which water is allowed to break in drops. It is obvious that if the potential of the reservoir be above that of the air surrounding the spot where the water breaks into drops, each drop will carry away with it a positive charge, and this will go on till the potentials are equalized. This device was introduced by Thomson in observations on atmospheric electricity. The burning match which he uses in conjunction with the portable electrometer acts in the same way. He has also constructed a water-dropping electric machine on a similar principle. Two streams of water break into drops inside two inductors connected with the internal armatures of two Leyden jars, A and B; the drops from each inductor fall into a receiver connected with the other inductor. A very small difference of potential between the jars starts or reverses the action of the apparatus; in fact, it will in general start of itself, and very soon sparks are seen passing between the different parts, and the drops are scattered in all directions by the strong electrical forces developed.

Holtz's machine.

The most remarkable, as well as the most useful, of all these machines is that of Holtz.[3] Here the convection is effected by means of a disc of glass, which is mounted on a horizontal axis F (fig. 58), and can be made to rotate with considerable angular velocity by means of a multiplying gear, part of which is seen at X. Close behind this glass disc is fixed another vertical disc of glass, in which are cut two windows, B, B. On the side of the fixed disc next the rotating disc are pasted two sectors of paper, A, A, with short blunt points attached to them, which run out into the windows towards the rotating disc, without quite touching it. Two metal combs C are placed on the other side of the rotating disc (that nearest the reader), the teeth being put opposite the parts of A, A which lie towards the windows. The combs are fixed to metal shanks, which pass through a stout horizontal bar of ebonite. One of these shanks terminates in a couple of balls at E, and the other carries a sliding electrode D with a long ebonite handle. The framework which carries the horizontal ebonite bar and supports the fixed plates, etc., will be understood from the figure.

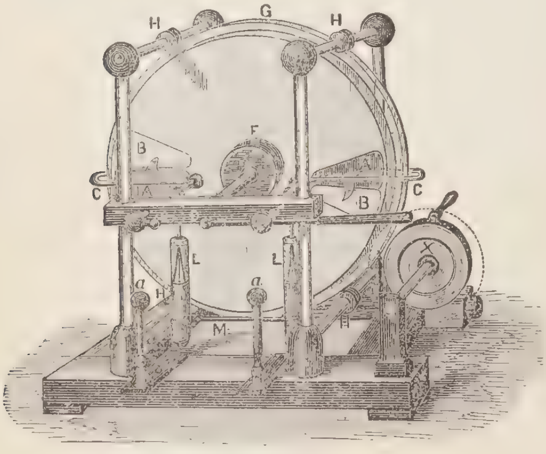

FIG. 58.—Holtz's machine.

The machine, as originally constructed by Holtz, contained only the parts we have described. Poggendorff doubled all the parts (except, of course, the electrodes D and E). The figure represents Ruhmkorff's modification of this construction. Behind the fixed disc there is another fixed disc, with windows and armatures like the first, and, beyond that, another movable disc mounted on the axis F. The combs are double, as will be seen from the figure. To start the machine, D and E are brought together, and one of the armatures (or one pair), say the right-hand one, is electrified in any manner, let us say positively, and the disc set in rotation. After a little time a hissing noise is heard, and the machine becomes sensibly harder to turn, as if the disc were moving through a resisting medium. If the room be dark, long curved pencils of blue light will now be seen issuing from the points of the left-hand comb, and running along the surface of the disc in a direction opposite to its motion, while little stars shine upon the points of the right-hand comb. After this state has been reached, the balls D, E may be separated, and a continuous series of brush discharges will take place between them, even when the distance is very considerable. If two Leyden jars, L, L, be hung upon the conductors which support the combs, the outer coatings being connected by a conductor M, then a succession of brilliant and sonorous sparks will take the place of the brushes. Instead of using the two jars L, L, we may connect D and E with the internal and external armatures of a condenser; it will then be found that, as we augment the capacity of the condenser (the angular velocity of the disc being constant), the frequency of the sparks diminishes, while their brilliancy increases. If we insert a high resistance galvanometer between D and E, it will indicate a current flowing from D to E, the intensity of which, under given atmospheric conditions and given state of the machine, will vary as the angular velocity, being independent, within very wide limits, of the resistance[4] between D and E.

It is not difficult to give a general account of the action of this machine, although it is very hard to assign the precise importance of the individual parts, very slight modifications of which greatly affect the efficiency. Suppose D and E in contact: the right-hand armature, charged +, acts by induction on the right-hand comb, causing — electricity to issue from the points upon the disc. At the same time the positive electricity of the right comb passes through DE to the left comb, and issues from its teeth upon the parts of the disc at the other end of the horizontal diameter. This + electricity electrifies the left armature — by induction, + electricity issuing from the blunt point upon the further side of the rotating disc. The charges thus deposited on the disc are carried along, so that the upper half is electrified — on both sides, and the lower half + on both sides, the sign of the electrification being reversed as the disc passes between the combs and the armature by the electricity issuing from the combs and from the armatures. If it were not for dissipation in various ways, the electrification everywhere would obviously go on increasing; but in practice a stationary condition is soon attained, in which the loss from the armatures is just balanced by the gain owing to the action of the blunt points. After this, both sides of the disc are similarly electrified, the upper half[5] always —, the lower always +; + electricity continually issuing from the points of the right comb, — electricity from the points of the left. This is, of course, accompanied by a current of + electricity from right to left through DE.

Modification of Holtz's machine.

The machine of Holtz, as we have described it, is somewhat uncertain in its action in our moist climate; but a slight modification of it gives excellent results. Upon the axis X is fixed a disc of ebonite, large enough just to reach between the paper armatures. This disc is fitted with a small rubber attached to the frame of the apparatus, and forms a small electric machine, which keeps the armatures continually electrified.[6] The whole is inclosed in a glass case, with a beaker of sulphuric acid to dry the air. There is a machine of this kind at present in the Cavendish laboratory at Cambridge, which never fails when the auxiliary apparatus is at all in good order.

A very remarkable phenomenon often occurs when the electrodes of Holtz's machine are in connection with the armatures of a condenser of considerable capacity, and are so far separated that a spark does not pass. The machine charges the condenser up to a certain point, and then the condenser discharges along the surface of the disc. If the experiment be conducted in a dark room, a flash of light will be seen to pass along the surface of the disc, and thereafter it will be observed that the long positive brushes have shifted from one comb to the other; after a little the condenser discharges again, and the brushes will now be seen in their old place, and so on. This phenomenon, though interesting to study, is often inconvenient in practice. To prevent it, Holtz introduced the diagonal conductor which is seen on many machines. For an account of this, and for other details concerning these machines, we refer the reader to Mascart, t. ii. § 847 *sqq.*, whose account of the most obvious principles of this apparatus is among the most lucid we have seen. His account of the experiment of causing one Holtz's machine in action to turn the disc of another by the electrical reaction is of peculiar interest.

Induction coil.

Electro-magnetic Induction Machines.—The type of these is the induction coil or inductorium, sometimes called Ruhmkorff's coil, after the great Parisian instrument-maker who first brought the instrument to perfection. The object of such machines is to obtain great electro-motive force from sources which furnish large quantities of electricity, but have only small electro-motive force.

---

[1] Jenkin, *Elect. and Mag.*, cap. xix.

[2] Described in the art. ELECTROMETER.

[3] *Pogg. Ann.*, 1865.

[4] We speak of resistances of 1 to 10,000 or 100,000 ohms.

[5] The line of division is not horizontal, however, if, indeed, it be exactly a diameter. See Mascart.

[6] Compare Carré's machine, Mascart, t. ii. § 856.

The principles on which the action is founded have been sufficiently indicated above in our section on the induction of electric currents. We have also given in the Historical Sketch (pp. 12, 13) some notices of the literature of the subject; a brief enumeration of the essential parts of the machine is all that is necessary here.

We have first the primary coil—of thick wire and few windings, so as to have a small resistance and a small coefficient of self-induction; the secondary coil surrounding the primary is of thin wire ($\frac{1}{10}$ mm. or so), with many windings, the length in large machines being often 100,000 metres. In order to avoid the danger of disruptive discharge between parts of the insulated wire, the coil is divided up by insulating septa, so that parts at very different potentials are separated. In the centre of the primary is placed a bundle of iron wires; this greatly strengthens the action, and a good deal depends on the quality of the iron, which should be very soft. The interruptor is simply a lever, worked by the coil itself or by an electro-magnet separate from the coil, by means of which the circuit of the primary is made and broken automatically. A variety of forms have been given to the part of the apparatus; the interruptor of Foucault is a very common one.[1] For some purposes a break driven by clock-work is used. The condenser, a very important part of the apparatus, is made of a number of sheets of tinfoil, interleaved with sheets of oiled silk or varnished paper. One set of leaves of the condenser is connected with one side of the break, and the alternate set with the other side. The function of the condenser is to provide a way for the electricity when the circuit is broken, and thus to prevent the intense spark of the extra current in the primary, which destroys the contact surfaces of the break, and, what is worse, prolongs the fall of the primary current, and thereby reduces the average electro-motive force of the induction current.

Other devices have been tried for effecting the same object as the condenser, such as inserting a fine metallic wire or an electrolyte as an alternative circuit to the break; and these answer the purpose to a considerable extent. An important improvement affecting this part of the apparatus has recently been introduced by breaking the primary circuit between the poles of a magnet, the effect of which is that the spark is suddenly drawn aside (blown out as it were). A considerable increase of striking distance between the poles of the secondary results from this arrangement.

ABSOLUTE MEASUREMENTS.

We have already indicated the considerations which determine the fundamental units in the two systems that have come into practical use. We ought now to explain how practical standards can be constructed to represent these fundamental units, or at least known multiples of them. It is necessary to have such standards in order that we may be able to measure electrical quantities in absolute measure by simple and expeditious methods of comparison, it being obviously impossible in practice to make absolute measurements directly on all occasions.

Measure of E. M. F.

Electro-statical System.—By means of Thomson's absolute electrometer we can determine any electro-motive force in absolute measure. In this way Thomson found the electro-motive force of Daniell's battery to be ·00374 C.G.S. electro-statical units.[2]

Resistance.

By using the absolute electrometer (see art. ELECTROMETER), or another that had been compared with it, we could by the method given above, p. 44, find a resistance (which was large enough to suit the method) in electro-statical measure.

Current.

Then, having standards of electro-motive force and resistance, we could easily measure a current in electro-static measure by applying Ohm's law. The same thing might be done by constructing the standard of quantity, which is the charge on an isolated sphere of unit radius charged to unit potential. By comparing the throw of a galvanometer when unit quantity is discharged through it with the deflection produced by any current, we could determine the latter in absolute measure by observing the time of oscillation of the galvanometer and the logarithmic decrement of its oscillation (see Maxwell, vol. ii. § 749).

Di-electric strength.

Among the absolute measurements in the present system of units, we must not omit to mention Sir Wm. Thomson's determinations of the di-electric strength of different thicknesses of air. From these, and from the measurement of the electro-motive force of Daniell's cell just mentioned, he concluded that a Daniell's battery of 5510 elements would be competent to produce a spark between two slightly curved metallic surfaces at $\frac{1}{8}$ of a centimetre asunder in ordinary atmospheric air.[3]

Electro-magnetic measure.

Electro-magnetic System.—The great majority of the absolute determinations hitherto made have reference to this system. We make no attempt here to instruct the reader concerning the details of this subject; such an attempt would lead us into technical particulars intelligible only to a few scientific men. We are fortunate, however, in being able to refer the English reader to two books which contain in a collected form all, or nearly all, the requisite information, viz., Maxwell's *Electricity and Magnetism*, and the collected Reports of the Committee of the British Association on Electrical Standards.[4]

Resistance.

As a specimen of the *theoretical* considerations involved, the reader may take Maxwell's method for determining the coefficient of self-induction of a coil (given above, p. 75). If we know the value of L (in centimetres) from calculation, then equation (33) might be used to find x in absolute measure. This would not be a practicable method, inasmuch as the calculation of L would be difficult if not impossible; we might, however, determine L by comparison[5] with a coefficient of mutual induction which *could* be calculated.

Kirchhoff.

The earliest absolute measurement of the resistance of a wire (by Kirchhoff in 1849) was of the kind just alluded to; that is to say, it involved the comparison of a resistance with a coefficient of mutual induction, the time measurement being that of the period of oscillation of a galvanometer.

Weber.

Weber used two methods,—(1) the method of transient currents, in which he measured the throw of a galvanometer caused by the current from an earth inductor of known area when it was turned about a vertical axis, so that the number of the earth's lines of force through it increased from zero to a maximum; and (2) the method of logarithmic decrements, in which he observed the time of oscillation and the logarithmic decrement of a magnet in a galvanometer of known constant. In the last of these two methods the horizontal component of the earth's horizontal force comes in directly, and the magnetic moment of the galvanometer magnet must be determined, which is a matter of great difficulty.

B. A. committee.

The determination of the British Association committee was carried out by Messrs. Maxwell, Balfour Stewart, and Fleeming Jenkin, and the result of it was the construction of a standard called the ohm, which professes to represent a velocity of an earth quadrant per second ($10^9\frac{\text{cm.}}{\text{sec.}}$).—The method they used is due to Sir Wm. Thomson. It consists essentially in causing a coil of wire of known dimensions to rotate about a vertical axis, and observing the deflection of a magnet of very small moment suspended at its centre.

Kohlrausch.

In a recent determination, F. Kohlrausch[6] has combined the two methods of Weber, and thereby avoided some of the difficulties which arise in either method used by itself. His value for the resistance of Siemens's mercury unit is $0{\cdot}9717\ \frac{\text{Earth quadrant}}{\text{Second}}$.

According to Dehms and Hermann Siemens, the resistance of the coil called the ohm is equal to 1·0493 mercury units. According to Kohlrausch, therefore, the actual British Association standard is $1{\cdot}0196\ \frac{\text{Earth quadrant}}{\text{Second}}$ in absolute measure; or, in other words, the determination of the British Association Committee is out by nearly 2 per cent.

Lorenz.

Lorenz[7] has, still more recently, made a determination of the value of the mercury unit in absolute measure. He causes a copper disc to rotate inside a coil of known dimensions. The two ends of a circuit C are kept in contact with the axis and circumference respectively of this disc. At two points A and B of C, the resistance between which is R, are attached the two terminals of the coil of wire, in circuit with which is also a battery. A sensitive galvanometer is placed in the circuit C, and the angular velocity of the disc is adjusted till this galvanometer indicates no current. If n be the number of revolutions per second, and E the electromotive force of induction per unit of inducing current, calculated from the dimensions of the coil, then the resistance R is equal to nE in electro-magnetic measure.

The result obtained by Lorenz for the value of the mercury unit is $\cdot 9337\ \frac{\text{Earth quadrant}}{\text{Second}}$; this would make the value of the B. A. standard $\cdot 9797\ \frac{\text{Earth quadrant}}{\text{Second}}$.

There is thus considerable discordance between the different results. It is a curious fact that the mean of the result of Kohlrausch and Lorenz gives for the value of the B. A. standard $\cdot 9996\ \frac{\text{Earth quadrant}}{\text{Second}}$. Fresh determinations are, however, in progress, and it is to be hoped that the doubt which hangs over the matter will be dispelled.[8]

[7] *Pogg. Ann.*, 1873.

[8] Since the above was written, an account has appeared of a new

Calorimetric method.

Besides these methods, there is yet another of a totally different character, originally suggested by Thomson in 1851, in his paper on the "Mechanical Theory of Electrolysis." This method consists in measuring the amount of heat developed in a wire by a current the square of whose strength is known in electro-magnetic measure. If we know the mechanical equivalent of heat with sufficient accuracy, we can calculate from these results the resistance of the wire in absolute measure by means of Joule's law. Measurements of this nature have been made by Von Quintus Icilius,[1] Joule,[2] and H. Weber.[3]

Current.

We can, by means of a tangent galvanometer, find the value of any current in electro-magnetic measure (see art. GALVANOMETER). If the resistance of the circuit be found, by comparison with the ohm or other absolute standard, we can determine the value of the electro-motive force in the circuit by Ohm's law. Measurements of this kind have been made by Bosscha,[4] by Von Waltenhofen, F. Kohlrausch, and Latimer Clark. The results of Kohlrausch[5] for the cells of Daniell and Grove, when no current is passing, are 1138×10^5 and 1942×10^5 C.G.S. units respectively. Latimer Clark[6] gives 1110×10^5 and 1970×10^5 for the same constants. The results, of course, depend on the constitution of the cells.

Taking the number of electro-magnetic units in an electro-static unit to be 3×10^{10}, we get from Thomson's electro-static measurements for the electro-motive force of Daniell's element 1120×10^5 in C.G.S. units.[7] The agreement among the different results is so far good.

Electro-chemical equivalent.

The determination of the electro-chemical equivalent of some elementary substance in this system of units is of great importance. Determinations exist by Weber, Bunsen, Casselmann, Joule, and F. Kohlrausch. The result of the last is no doubt the best, as he combined with his voltametric experiments a determination of the horizontal component of earth's magnetic force, which is the most uncertain factor in the result. According to his result, one C.G.S. unit of electricity deposits ·011363 (± ·000002) gm. of silver. From this we get for the electro-chemical equivalent of water ·0009476.

Measurement of the fundamental velocity.

Ratio of Electro-static to Electro-magnetic Unit.—If we measure the same quantity of electricity first in electro-static and then in electro-magnetic measure, the fundamental units of mass, length, and time being the same in both cases, the ratio of the two measures will vary directly as the magnitude of the unit of length, and inversely as the magnitude of the unit of time adopted. This ratio may therefore be regarded as a velocity which will remain the same whatever three fundamental units we adopt.[8]

Weber and Kohlrausch.

This velocity was found by Weber and Kohlrausch by the direct process of measuring the same quantity of electricity, first in terms of the one unit and then in terms of the other. This result was $31 \times 10^9 \frac{\text{cm.}}{\text{sec.}}$.

Maxwell, Thomson.

Five other methods will be found described by Maxwell, vol. ii. § 768 *sqq.* Two of these have actually been carried into execution,—one by himself, the other by Sir Wm. Thomson. The results for the fundamental velocity are $28{\cdot}8 \times 10^9 \frac{\text{cm.}}{\text{sec.}}$ and $28{\cdot}2 \times 10^9 \frac{\text{cm.}}{\text{sec.}}$ respectively.

THEORIES OF ELECTRICAL PHENOMENA.

Speculative theories, etc.

Throughout this article we have limited ourselves as much as possible to an exposition of the experimental facts of electricity. Where mathematical developments have occurred, they have in most cases been simply deductions from some principle or principles well established by experience. To have made our survey of the present state of electrical science complete, we ought to have added a section on the different attempts which have been made by the doctors of the science to penetrate a little farther into the secrets of the hidden mechanism by which electrical phenomena are brought about. But any attempt at a review of this kind must be relinquished. We refer the reader to our indications of the literature (Historical Sketch, p. 11). The most important work in this department lies at hand for the English reader in Professor Clerk Maxwell's *Treatise on Electricity and Magnetism.*[9] Particularly important are his theory of electric displacement and its application to statical as well as to current electricity; his investigation of the stresses in the medium, by which the electrostatical forces on the one hand, and the electro-magnetic forces on the other, may be produced; the application of the theory of displacement to the case of electrical equilibrium when the di-electric medium is not everywhere the same; the dynamical theory of the electro-magnetic field; and the electro-magnetic theory of light. Maxwell gives, at the end of his work, a most instructive summary of the different speculative theories. The student who desires to pursue this department farther will do well to master this summary at the outset. (G. CH.)

INDEX.

The figures refer to the pages.

Absolute measurements, 97, 98; history of *Gauss, Weber*, B. A. Committee, etc., 15.
Accumulator, theory of, 32.
Alternating discharges with Inductorium and Leyden jar, 61.
Ampère, electro-dynamics, 10.
Ampère's law, 66; experimental arrangements for showing electro-dynamical action, 66.
Ampère's theory, sketch of, 70; generalization of, 70.
Arc, voltaic, 55.

Batteries, 87, 88; history of, 13; one-fluid and two-fluid —oxidizing agents in—local action — polarization, etc., 87.
Battery of Leyden jars, 33.
Bound and free electricity, 33.
Bowl, spherical, distribution on, *Thomson*, 32.
Brush, 59.

Capacity, coefficients of, 26.
Cascade, jars in, 33.
Cell of *Daniell*, different modifications of, 87, 88; of *Grove, Bunsen*, etc., 88.
Chemical affinity, electrical measure of, *Joule*, 86.
Circuit, linear, *Ohm's* law for, 39; action on, in magnetic field, 64.
Circular current, magnetic action of, 67.
Condensing electroscope, 32.
Conduction, *Gray*, 5; general equations of, 39.
Conductivity boxes, 43.
Conductors, network of linear, *Kirchhoff*, 40; conjugate, 41.
Conjugate functions, 32.
Conservation of energy, *Joule*, etc., 14.
Contact force, general law of, 78; *Volta's* experiments, 78; *Volta's* law, 78; *Kohlrausch's* researches, 79; *Hankel's* experiments, 79; *Thomson's* demonstration, 80; *Clifton's* experiments, 80; uncertainty concerning, 80; from polarization, 81.
Contact of conductor with non-conductor, 93.
Contact of non-conductors, 93.
Convection, electrolytic, *Helmholtz*, 82; of heat, electric, *Thomson*, 90; *Tait's* conjecture concerning, 90.
Convective discharge, 60, 61.
Convecto-inductive machines, *Holtz, Töpler, Varley, Thomson*, 94, 95, 96.
Coulomb, 9; his torsion balance, 17.
Current, electric, general phenomena and measure of, 38.
Currents, mutual action of, when parallel and when inclined, 66.

Decomposition of alkalis, *Davy*, 9; of water by electric current, *Nicolson* and *Carlisle*, 9; by electric spark, 9.
Di-electric strength of gases, etc., *Harris, Riess*, etc., 57; effect of pressure, etc., on, *Harris*, 57; *Faraday's* researches on, 57; *Wiedemann, Rühlmann*, 58; at high pressures, 58; minimum for vacuum, 58.
Differential galvanometer, 41.
Discharge in fluids, 62; in solids, 62; in gases, magnetic action on, *De la Rive* and *Plücker*, 70.
Disruptive discharge, 56–63; theoretical considerations on, 58; progress of, 58.
Distribution, electrical, *Coulomb*, 19, 21–23; general problem of, 25.
Doubler, *Bennet's, Darwin, Cavallo*, and *Nicholson*, 95, 96.

Earth's action on suspended current, 68.
Electricity, positive and negative, *Dufay*, 6; theory of 16.
Electrics and non-electrics, *Gilbert* and *Boyle*, 5.
Electrodes, temperature of, in discharge through gases, 61.
Electro-dynamics, theory of, *Ampère, Weber, Neumann, Helmholtz, Maxwell*, 11, 62–69.
Electro-dynamometer, use of, in measuring electrolytic resistance, 46; *Weber's* experiments with, 67; *Ampère's* theory verified by means of, 67.

ELECTROLYSIS. A very slight acquaintance with the phenomena of conduction of electricity by different bodies shows us that conductors may be arranged in two very distinct classes. In one the passage of electricity produces no change in the chemical composition of the substance, unless indeed the electro-motive force be so great that disruptive discharge occurs, or so large an amount of heat is generated that chemical effects ensue; the conductivity diminishes slowly as the temperature rises, and if the resistance of the rest of the circuit be small compared with that of the substance under consideration, an amount of heat is produced in the latter equivalent to the energy expended by the sources of electricity. To this class of conductors probably belong all solids, with the exception of hot glass, which conducts with decomposition at a temperature below the fusing point. The conductivity differs enormously in the different cases; those which conduct most readily are the metals, alloys, the chemical elements generally, and some few metallic oxides and sulphides (Faraday, *Exp. Res.*, 440, ser. iv.; Skey, *Chem. News*, xxiii.). Besides fused metals Faraday added one liquid, fused periodide of mercury, to the list, but subsequently gave reasons for considering that it was misplaced (*Exp. Res.*, 691, ser. vii.). The other class of conductors presents a remarkable contrast to the one just described. In these the passage of electricity results in the chemical decomposition[1] of the substance of the conductor at the points where the electric current[2] enters and leaves the body; a rise of temperature produces in such bodies a very considerable increase in the conductivity, but the specific resistance of even the best conducting among them is always very great compared with that of the metals. (For details see article ELECTRICITY, p. 44 *sqq.*) Only part of the energy of the circuit is spent in heating the conductor, as a transformation of energy takes place in the chemical and molecular actions at the points where the current enters and leaves the conductor.

It is the behavior of the second class of bodies under the influence of the electric current that we have now to discuss. The physical side of the subject has already been considered in the article ELECTRICITY; so we shall principally confine our attention to the phenomena of electrolysis which bear on the laws and principles of chemistry. Before going further it will be necessary to introduce the technical terms which have now become familiar, and, in order to be definite, we will consider somewhat closely a particular instance of electro-chemical decomposition of the simplest type.

Typical electrolytic action.

The cell in which the action takes place consists of a wide tube of hard glass, bent into a V-shape; into this is introduced some silver chloride, which is kept fused during the experiment; into the liquid in one leg of the tube is dipped a platinum wire connected with the negative pole (zinc) of a battery[3] of 3 or 4 Grove's cells, and into that in the other a piece of graphite or gas carbon connected with the positive pole of the same battery. We will suppose a galvanometer introduced into the circuit, and that the current strength as indicated thereby is, roughly speaking, constant, so that the quantity of electricity which passes can be measured roughly by the time occupied in passing. After the circuit has been closed a short time, bubbles of chlorine will begin to come off from the carbon, while pure silver is deposited upon the platinum wire, but *except at these points no alteration will take place at any part of the fluid.* If the platinum wire with the attached silver be weighed at intervals, it will be found that the amount deposited after the current has become constant is proportional to the time, *i.e.*, to the amount of electricity which has passed through the liquid. The same will be true of the chlorine if collected in the other leg of the tube, due allowance being made for the small bubbles retained by the carbon, etc. And the amount of chlorine will be chemically equivalent to the amount of silver; thus for every 108 grammes of silver on the platinum there will be 35·5 grammes of chlorine set free in the other leg of the tube. Moreover if the current be varied by varying the number of battery cells, it will be found that the amount of decomposition in a given time is proportional to the current, that is, again, to the quantity of electricity which traverses the substance.

Nomenclature.

Faraday, who was the first to define the laws which hold in electro-chemical decomposition, introduced, for the sake of precision, a system of nomenclature which has since been generally employed. Wishing to regard the terminals corresponding, in any similar case, to the carbon and platinum in the above experiment merely as the "doors" by which the electricity enters and leaves the liquid, he denominated them *electrodes*, and, comparing the "path" of the current to those of the currents which may produce terrestrial magnetism, and hence to the course of the sun, he called the homologue of the carbon (where the current, so to speak, "rose," or entered) the *anode*, that of the platinum (where the current "set," or left) the *cathode*. The component parts, no matter how complex, into which the liquid was decomposed, corresponding to the Ag and Cl of the above, received the name of "ions"—that component which went *down* with the current to the cathode, and there either was set free or combined with the cathode or the surrounding liquid, being the *cation*, and that which went *up* against the current, and appeared or promoted some chemical action at the anode, the *anion*. Moreover, the substance decomposed was called an *electrolyte*, and the process itself *electrolysis*. (Faraday, *Exp. Res.*, 662 *sqq.*)

The phenomena which occur at the electrodes when the ions there set free react upon the electrode or the surrounding fluid, so that the resulting products of electrolysis are not the ions themselves, are called *secondary actions*.

The anion and the cation are frequently called the negative and positive ion respectively. Similarly the cathode and anode are termed the negative and positive electrodes; Daniell denoted them the platinode and the zincode, but these terms have fallen into disuse.

What bodies are electrolytes.

Of the bodies which are capable of electrolytic conduction nearly all, if not all, are liquids. Faraday (*Exp. Res.*, 433, 1340) apparently obtained some chemical decomposition in sulphuret of silver and a few other salts when solid, but this did not alter his opinion that the mobility secured in the fluid state, either by fusion or by solution, was necessary to the phenomena of electrolysis; and his view, which he supported by experiments on ice and other solids that conduct when fused (*Exp. Res.*, 380–397, 419–428), still obtains. Electrolytic action doubtless sometimes takes place in gases, but accurate investigation of the subject is difficult on account of the extreme mobility of the particles and the danger of confusing electrolytic effects with effects due to disruptive discharge by convection. Gases have, however, been decomposed by the silent discharge, as CO_2 into $CO+O$.

From Faraday's time attempts have continually been made to classify strictly, according to their chemical composition or constitution, the liquids capable of electrolytic conduction, but hitherto without very much success. It must be remembered that, as the resistance of a liquid increases, the tests of electrolytic conduction become less and less sensitive. We can consider a body an electrolyte if we can (1) collect the products of decomposition, or (2) demonstrate their presence on the electrodes by means of the return current due to polarization. If the resistance be very great the former method becomes evidently very difficult, and in the latter complications are introduced which cannot here be discussed (see ELECTRICITY). On the other hand, we might easily be misled into considering a body an electrolyte from the presence of mere traces of a foreign substance. Thus at one time water was regarded as the only electrolyte, but it is found that the purer the water is the less does it conduct electricity, and now Kohlrausch and Nippoldt have shown that the presence of one 10-millionth of H_2SO_4 would be sufficient to account for its observed conducting power, so that the weight of evidence goes to show that water itself is not an electrolyte at all.

It is not, then, surprising that views on the question of what constitutes an electrolyte have changed considerably. Davy and the older chemists, as mentioned above, considered water to be the only electrolyte; Faraday, by electrolyzing fused chlorides, etc., dissipated these notions, but still regarded water as the electrolyte which was decomposed when acids were subjected to the electric current, and his general conclusion was that an electrolyte must be a compound consisting *of an equal number of chemical equivalents of its elements*, that is, in modern notation, must be of the type $M_y^{(x)}R_x^{(y)}$ where x and y are the atomicities or valencies of the elements whose *atomic weights* are represented by M and R, and thus that two elements would by uniting form only one electrolyte (*Exp. Res.*, 679–701, 830). The oxygen salts for which Faraday assigned no law were included by

---

[1] We have not space here to discuss whether or not conduction in electrolytes is always attended with decomposition, although the question has engaged the attention of many writers on the subject. The reader who wishes for information upon the point may consult Faraday, *Exp. Res.*, 966–987½, ser. viii.; Despretz, *Compt. Rend.*, t. xlii. p. 707; De la Rive, *Archives*, t. xxxii. p. 38; Logeman and Van Breda, *Phil. Mag.* [4], viii. 465; Buff, *Ann. d. Chem. u. Pharm.*, Bd. xciv. s. 15; Foucault, *Compt. Rend.*, t. xxxvii. p. 580; De la Rive, *Ann. de Chimie*, [3], t. xlvi. p. 41; Favre, *Compt. Rend.*, lxxiii. p. 1463; Helmholtz, *Berlin Monatsbericht*, 1873, Nachtrag zum Juliheft; and for a summary of results, Wiedemann, *Galv.*, Bd. i. §§ 314–316, and Nachtrag, 36, § 334.

[2] The standard direction of the current is taken, as usual, to be from the copper through the wire to the zinc of an ordinary zinc-copper cell.

[3] It is not *necessary* to use a voltaic battery,—any source of electricity serves,—but either a voltaic or a thermo-electric battery is usually employed, since these so conveniently supply a large *quantity* of electricity, with an electro-motive force sufficient for the purpose.

Daniell in the same formula as binary compounds, of which the part R acting as anion was no longer an element but a compound; thus $ZnSO_4$ was shown to be split up by electrolysis into Zn and SO_4; in that case *y* would represent the basicity of the acid forming the salt.

This hypothesis lacks definiteness, on account of the variation of the atomicity of the elements, and falls through altogether in the case of copper and iron, which form each two chlorides, ($CuCl_2$,Cu_2Cl_2), ($FeCl_2$,Fe_2Cl_6), both electrolytes and in consequence Wiedemann (*Galv.*, Bd. i. §§ 295,346a, 418 (5)) modifies the statement of the hypothesis, and considers that for a body to be an electrolyte it must be capable of formation by double decomposition from one of the simple binary electrolytes, the exchanging atoms or groups of atoms forming the ions of the new compound. Thus silver acetate gives, by double decomposition with sodium chloride, silver chloride and sodium acetate. Sodium acetate and silver chloride are therefore electrolytes of which Ag, Cl, Na, $C_2H_3O_2$ are the respective ions. This hypothesis may be illustrated by a great number of instances:—the case of the decomposition of uranium compounds, as UOCl into UO and Cl, is a very good example. But Wiedemann's view would indicate that a body, in order to be an electrolyte, need but be one of a "series of salts," and we then see no reason for excluding the hydrogen salts from the class; thus H_2O and HCl can be easily formed by double decomposition, yet the former is, when pure, one of the worst liquid conductors, while the latter as liquefied gas is apparently not decomposed even by 5640 cells of De la Rue's chloride of silver battery, but gives vibrations indicating very high resistance.[1] Bleekrode has also shown that, of all the pure liquefied hydrogen acids, only HCN is an electrolyte. On the other hand, liquefied NH_3, which is not formed, so far as we are aware, by double decomposition, is electrolyzable by only a moderate battery of Bunsen's cells, giving a blue liquid at the cathode. Moreover, Buff (*Ann. d. Chem. und Pharm.*, Bd. cx.) has electrolyzed molybdic and vanadic anhydrides after the manner $MoO_3 = MoO_2 + O$, but these bodies are not obtainable by double decomposition with a simple electrolyte.

Miller (*Elements Chem.*, i. § 282 (*v*)) considers that an electrolyte must be a combination of a conductor and a non-conductor, and so the majority of electrolytes are. But alloys behave to a certain extent as electrolytes when fused (see Wied., *Galv.*, Bd. i. § 328), and $SnCl_4$, though consisting of a conductor and a non-conductor, is not an electrolyte; so that this classification is not exclusive.

It would therefore appear that the condition does not lie in the chemical constitution of the body, but rather in its molecular state, and to this points the fact that two non-conductors, as H_2O and HCl, on being mixed form a very good conductor. In addition to this, quantitative measurements of the resistance of electrolytes show that, in the case of many salt and acid solutions, there is a point of concentration below saturation, for which the conductivity is a maximum. This would scarcely be the case if one alone of the bodies were the conductor.

The liquids which do not conduct are very various, including, besides oils and resins and other organic bodies, benzine, iodide of sulphur, carbon disulphide, glacial acetic acid, fused boracic anhydride, antimonic oxide and oxychloride, the higher halogen salts of tin, liquid sulphurous anhydride, pure water, and pure halogen acids. For others see article ELECTRICITY, p. 48.

Faraday's law for a single electrolyte.

In the description of the phenomena, in the typical case of electrolysis given above, it was stated that the amount of chemical decomposition in any time is proportional to the whole quantity of electricity which passes through the liquid in that time; this is true in all cases of electrolysis, and was established by Faraday (*Exp. Res.*, v. 505, and ser. vii.). It forms part of the general law to which his name is attached, but we prefer to consider it separately for reasons that will appear when we discuss the statement of that law. We may put it thus:—*If* W *be the mass of an electrolyte,*[2] *decomposed by the passage of a quantity* E *of electricity, then, as long as the ions remain of the same nature,*

$$W = KE, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (1)$$

where K *is a constant dependent only on the nature of the electrolyte, and therefore independent of the nature or size of the electrodes and of any secondary actions which may take place.*

Voltameters.

It is evident that if we can prove the truth of this law for one electrolyte, with ions which do not vary with variations of electro-motive force, we shall have a very convenient means of measuring the total amount of electricity which passes through any circuit in a given time by introducing such an electrolyte into the circuit, and measuring the amount of decomposition in the given time. Faraday demonstrated the truth of the law in the case of dilute sulphuric acid by experiments with vessels in which the products of decomposition of the dilute acid between platinum electrodes could be conveniently collected, either separately or together, and measured (*Exp. Res.*, 714–728). Such an instrument he called a volta-electrometer, and subsequently a voltameter. After demonstrating that the amount of decomposition was independent of the size of the electrodes he connected up two voltameters A and B, in multiple arc, as in the accompanying diagram, and then passed the whole current through a third C, and found that the amount of decomposition in C was equal to the sum of the amounts in A and B. He therefore applied the voltameter[3] to measure quantities of electricity in other cases.

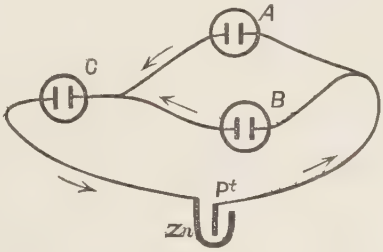

Diagram showing connection of voltameters.

Various forms of voltameter have been employed (see Wiedemann, *Galvanismus*, Bd. i. §§ 317–319). The most accurate is the silver voltameter of Poggendorff, which consists of a vertical rod of silver with the lower end immersed in a solution of silver nitrate contained in a platinum vessel; the silver is connected with the positive, the platinum vessel with the negative pole of the battery, and the amount of decomposition is ascertained by weighing the platinum vessel with the attached silver before and after the experiment. Buff directly proved the truth of equation (1) for such an instrument by electrolyzing silver nitrate solutions of different strengths between silver electrodes. The currents employed were varied for different experiments, and were measured by a tangent galvanometer, and the quantity E of electricity was deduced by observing the time of passage of the current. (*Ann. d. Chem. u. Pharm.*, xciv. 15.)

We have, then, in order to demonstrate generally the law expressed in equation (1), to measure the amount of the ions set free in any case of electrolysis, while the amount of electricity is measured at the same time by means of a voltameter included in the circuit. But the measurement of the amount of ions liberated is not always an easy task; in the great majority of cases secondary actions (see above, p. 100) occur, the primary results of electrolysis are obscured, and in order to determine the nature and amount of the ions special apparatus and further investigation are necessary.

Determination of the ions.

Since the ions are liberated at the electrodes the products of secondary action will remain in the immediate neighborhood if the action be not too long continued. We may therefore determine the ions by collecting any gaseous products, ascertaining the loss or gain in weight of the electrodes, and analyzing the electrolyte in the immediate neighborhood of the electrodes, taking care that the products at the two do not mix by gravitation, by diffusion, or otherwise.

---

[1] Bleekrode and De la Rue, *Proc. Roy. Soc.*, xxv. p. 323. In fact, disruptive discharge occurs by convection currents, or, if the electrodes be sufficiently near, by spark. Similar phenomena may be observed by immersing the poles of a Holtz machine in paraffin oil.

[2] In what follows, the term electrolyte is used in its most general sense, to signify any liquid or mixture of liquids through which the current passes, and not necessarily one definite chemical compound. Hence the necessity for the condition that the ions shall not vary, as in mixed electrolytes ions for high electro-motive forces are different from those for low (*vid. inf.*).

[3] Many corrections have to be applied to the observations with a water voltameter in consequence of—(1) the formation of ozone in the collected oxygen; (2) the formation of H_2O_2; (3) the solution of the evolved gases in the water, varying with different strengths of acid, and greater for oxygen than hydrogen; (4) the re-combination of the oxygen and hydrogen if in contact with platinum (see Wied. *Galv.*, *l. c.*). A diagram and description of the water voltameter will be found in any of the numerous works on the subject.

For instance, if a fused chloride (*e.g.*, $PbCl_2$) be electrolyzed with platinum electrodes, no chlorine will be evolved at the anode, although Pb will be deposited at the cathode; but if the liquid round the anode be analyzed, for every 414 grammes of lead at the cathode will be found 339 grammes of $PtCl_4$ round the anode. Now the platinum must have been derived from the anode, which will be found to have lost 197 grammes in weight, consequently the 142 grammes of Cl were derived by the electrolysis from the $PbCl_2$, and hence $PbCl_2$ is electrolyzed as $Pb + Cl_2$.

In order to separate the fluids at the two electrodes, various forms of apparatus have been employed. For fused electrolytes a W-shaped tube, which can be divided after the fluid has solidified, is sufficient; with solutions, however, where the solvent introduces new complications the separation is more difficult, owing to the "migration of the ions" and other causes which will be considered below. Daniell and Miller (*Phil. Trans.*, 1844) used a cylindrical glass vessel separated into three compartments by porous clay diaphragms, the two end compartments containing the electrodes, and having tubes for conducting away gaseous products; while Hittorf, in a classical series of experiments (*Pogg. Ann.*, lxxxix., xcviii., ciii., cvi.), used a number of bell-shaped glass vessels fitted to each other with india-rubber washers, the electrodes being inserted in the bottom and top vessels respectively. The lower end of each bell was covered with membrane to prevent mixing of the products; the whole apparatus was filled with the electrolyte to be decomposed; and the products at the two electrodes were known to be separated if the composition of the fluid in one of the intermediate bells remained the same throughout the experiment.

Great numbers of experiments have been made by different experimenters in one or other of the ways mentioned, and they have thus proved that, whatever the electrodes, and whatever the electro-motive force, the secondary action at the electrodes has no effect upon the amount of chemical decomposition,[1] and therefore the law of equation (1) always holds.

Secondary actions.

We can give here but a few examples of secondary action. A very good account will be found in Wiedemann, Bd. i. §§ 326–385, with, however, the drawback of the use of an obselete chemical notation.

(1.) *The ions themselves are set free, but separate into component parts.* That this is the case with oxygen salts, which are separated into the metal and a complex anion which is resolved into oxygen and an anhydride, was pointed out by Daniell (*Phil. Trans.*, 1839), who gave to the SO_4, derived as electro-negative ion from sulphates, the name of oxysulphion, and so on. Many similar cases occur in electrolyses of organic compounds. Thus potassium acetate is electrolyzed originally as $KC_2H_3O_2 = K + C_2H_3O_2$; but the anion splits up (partly at least) thus: $2C_2H_3O_2 = C_2H_6 + 2CO_2$. All the potassium salts of the fatty acids behave similarly, so that this becomes a general method of preparing the normal paraffins.

(2.) *The ions appear in an abnormal molecular state.* The deposit of copper in Gladstone and Tribe's ZnCu couple is a black crystalline powder (see p. 107). The most important instance, however, is the formation of ozone in the oxygen liberated at the anode by the electrolysis of acid solutions, which was recognized by Schönbein in 1840, although the smell and powerful oxidizing properties of the gas evolved had previously been noticed by Franklin and Van Marum. The amount of ozone, though very small, may be recognized by all the ordinary tests (KI, indigo, etc.); it diminishes with rise of the temperature at which the electrolysis takes place, and is above 2 per cent. when the electrolyte dilute H_2SO_4 is cooled by ice and salt, and the electrodes are platinum-iridium wires (Soret). With dilute H_2SO_4 at 6° C., 100 c. c. of oxygen contained ·00009 gramme ozone and ·00027 at a mean temperature of $-9°$ C.; dilute H_2CrO_4 gave at 0° C. ·00052 gramme per hundred c. c. of oxygen (Soret). The amount varies with the different acids, solutions of chromic and permanganic acids giving the largest percentage.

These points are of importance in correcting observations by the water voltameter.

The molecular state of the deposit varies very much with the density of the current, *i.e.*, the current strength per unit area of electrode (Bunsen, *Pogg. Ann.*, xci. 619). With small current density the metals are deposited as well-shaped crystals; on increasing the density, reguline metal (similar to the metal when smelted) is obtained, but with great density the deposit is amorphous, botryoidal, or pulverulent. With some metals, the molecular state differs with the solutions from which they are deposited. Thus silver from dilute solution of the nitrate, with great current density, appears as a black powder, becoming gray-white and crystalline when the current ceases (Wied. *Galv.*, Bd. i. § 336a) but from solution of potassium silver cyanide it is electrolyzed as reguline metal. Gold and platinum exhibit a similar behavior. For a good instance of amorphous deposit, see the account of Gore's explosive antimony in his *Electro-metallurgy*, p. 103.

(3.) *The ions very frequently react upon the electrodes,* and produce in some cases very interesting chemical actions. If the cation and cathode are both metals, an alloy of the two is the usual if not universal result. This is well known in the case of the electrolysis of many metals and salts with mercury electrodes, and the combination of the hydrogen set free by electrolysis with electrodes of palladium, nickel, and iron may be similarly regarded; and perhaps the compounds derived when ammonium salts are decomposed with a mercury cathode. Copper, when deposited on platinum, alloys with it to a certain extent, the alloy penetrating to a considerable depth (Gore, *Electro-metallurgy*, p. 47). Faraday noticed the combination of tin and lead with platinum electrodes in the electrolysis of the fused salts of those metals.

The action of the anion upon the anode furnished Faraday with an accurate and convenient means of estimating the amount of chemical decomposition produced by a definite quantity of electricity, and thereby of confirming the law given by equation (1) (*Exp. Res.* 807–822). Thus by varying the anodes, while the cathode remained the same, in the decomposition of acidulated water he found the amount of hydrogen liberated at the cathode, and therefore the chemical decomposition, independent of the nature of the electrodes; and by electrolyzing various chlorides, as of silver, tin, lead, with an anode of the same metals respectively, he was enabled to determine very accurately the amount of chlorine separated. We shall have more to say on the bearing of this hereafter. The oxygen liberated by the electrolysis of acidulated water frequently unites with the anode; even if this is of carbon it becomes oxidized to CO and CO_2; this was noticed by Faraday (*Exp. Res.*, 744), and is interesting as showing the active state of the oxygen when separated.

Electro-capillary phenomena.

But perhaps the most interesting examples of the action of the ions on the electrodes are furnished by the capillary phenomena exhibited by mercury in contact with dilute acid, on the passage of the current. If we have a drop of water upon a surface of Hg, and the water be connected with the positive, while the Hg is connected with the negative pole of a battery, the water will gather itself up into a spherical drop, and on reversing the current will spread itself over the metal. This phenomenon is supposed by Wiedemann to be due, in the former case, to the reduction of a film of oxide on the surface of the Hg by the liberated H, thereby giving a cleaner surface with a higher capillary constant, and, in the latter, to the oxidation of the surface by the liberated oxygen; and this view is borne out by numerous experiments. Thus a reducing agent, such as crystal of sodium thio-sulphate ($Na_2S_2O_3$), introduced into the drop of water produces similar contraction of the drop, while an oxidizing agent, as $K_2Cr_2O_7$, produces on the contrary a similar dispersion. A drop of Hg in dilute sulphuric acid, connected with the positive pole of a battery, while the negative electrode is near it, extends toward that electrode on the passage of the current, becoming covered with a film of suboxide, which then dissolves in the H_2SO_4, and leaves again a bright surface, when the drop returns to its original position, and a series of oscillations are thus set up (see Wied. *Galv.*, i. 368 *sqq.*). With solutions of alkaline cyanides containing mercury Gore obtained oscillations producing sounds (*Elec.-Metall.*, p. 197; *Proc. Roy. Soc.*, 1862). It was observed by Erman that a drop of mercury in a horizontal tube, with dilute acid on both sides, moved at the passage of the electric current through the tube towards the negative electrode. These phenomena have been investigated further by Lippmann (*Pogg. Ann.*, cxlix. 547, trans. in *Phil. Mag.* [4] xlvii. 281). One of the forms of his apparatus is as follows. A glass tube A, drawn out to a short capillary point of about $\frac{1}{100}$mm. radius, contains mercury which penetrates into the fine point and partly fills it, the remainder being filled with dilute H_2SO_4, into which the capillary opening dips; below the electrolyte is a surface of mercury, serving as the positive electrode, sufficiently broad for the capillary effects there to be neglected. The negative electrode is the mercury in the tube A. Lippmann showed by this apparatus that, in order to compensate the change in the capillary constant of the mercury produced by a definite electro-motive force of polarization, a definite increase of pressure on the mercury in A is required. As for an electro-motive force of polarization equivalent to a Daniell cell the compensating pressure was 260 mm., and as the quantity of electricity required to polarize the electrodes is very small, this apparatus, when once it has been graduated by observing the compensating pressure for known electro-motive forces, may evidently be employed as a sensitive and convenient electrometer for electro-motive forces less than the maximum of polarization of the electrodes.

---

[1] Of course, if the products of decomposition be allowed to accumulate until the electrode is surrounded with an envelope of liquid differing from the original electrolyte, the whole character of the decomposition changes.

Passivity. We may mention one other example of the action of the ions upon the electrodes. An iron wire is usually attacked by dilute HNO_3 (sp. gr. 1·3); but if previously to its being immersed in that liquid it is employed as the anode in the electrolysis of diluted oxygen acids, the nitric acid has no longer any effect upon it, not even tarnishing the surface, and the wire differs from ordinary iron in being strongly electro-negative to it, and indeed to copper, in dilute acids (Martens, *Pogg. Ann.*, lxi. 121). It is then said to be in the *passive state*, and is considered to be covered with a film of oxide which is strongly electro-negative, and insoluble in dilute nitric acid (Faraday, *Phil. Mag.*, ix. p. 60, 1836, x. p. 175, 1837; Beetz, *Pogg. Ann.*, lxii. 234, lxiii. 415). De Regnon, however (*Comptes Rendus*, lxxix. 299), attributes the phenomena to polarization. This peculiar state may be induced by various processes; Keir (*Phil. Trans.*, 1790) observed it when an iron wire was dipped into strong nitric acid (sp. gr. 1·5), by which its surface is not attacked. A more dilute solution has the same effect (Schönbein, *Pogg. Ann.*, xxxviii. 444), if the wire be immersed several times, or if the solution contain chromic or sulphuric and permanganic acids (Boutmy and Chateau, *Cosmos*, xix. 117). Iron when dipped in very strong solution of $AgNO_3$ does not precipitate the silver, and is electro-negative even to that metal. Another method of rendering iron passive, evidently the same in principle as the one first mentioned, is to touch the iron wire immersed in dilute nitric acid, by carbon, platinum, or other electro-negative element itself in contact with the liquid; and on the contrary, passive iron becomes active if it be touched by a body electro-positive to it, as copper or zinc. If a passive wire be partly immersed in the dilute acid, and an active wire in contact with it be *slowly* introduced into the liquid, the latter becomes passive too; but if they touch under the surface, both are rendered active. Iron is rendered passive also by heating in a current of oxygen or an oxidizing flame until it is tarnished. On the other hand, the passive metal becomes active under the influence of any reducing action upon its surface, whether by deposition of H upon it by electrolysis, by heating the metal in a reducing flame, or by abrading the surface. One modification of the electrolytic method is to touch the metal in dilute nitric acid, for a moment, with a copper wire. The point touched becomes immediately active, and therefore electro-positive to the rest, and so currents are set up from active to passive metal through the acid, which accordingly reverse the state of both parts, and a curious series of oscillations result, ending in the whole becoming active. (Schönbein, *l.c.* Compare these with the phenomena of alternation of passive and active states of iron, and of the oxidized and bright surfaces of amalgamated zinc described by Joule, *Phil. Mag.*, 1844, i. 106.)

Iron is not the only metal which behaves thus. Nickel, cobalt, tin, bismuth, and even copper, all exhibit similar phenomena in strong HNO_3 and as positive electrodes; and aluminium thus treated is electro-negative even to passive iron (see Wiedemann, *Galv.*, Bd. i. §§ 539–542).

Secondary actions. (4.) *The ions act upon the fluid surrounding the electrodes.* Actions of this kind in both fused and dissolved electrolytes nearly always occur unless the ions combine with the electrodes; thus perchlorides, if such exist, are formed from the chlorides, and perchlorates from chlorates at the anode (Kolbe). At the cathode the secondary actions are cases of reduction; thus if solution of potassic iodide be electrolyzed, corresponding to 1 equivalent of iodine at the anode, there will appear not only 1 equivalent of H, at the cathode, but an equivalent of KHO as well, so that the potassium liberated from the iodine must have acted upon the water and formed KHO. If ammonium chloride be electrolyzed, the chlorine at the anode reacts upon the NH_4Cl, giving free nitrogen and nitrogen-chloride. The electrolysis of ammonium nitrate is still more interesting, as NH_3 and H are separated at the cathode, where the hydrogen reduces the nitric acid of the nitrate, and nitrogen is evolved, while at the anode NO_3 is deposited, which forms with the water nitric acid and oxygen, the latter reacting upon the ammonia of the nitrate, again evolving nitrogen, so that that element appears at both poles,—at one mixed with ammonia, at the other with oxygen (Miller). Some of the reactions investigated by Kolbe and Burgoin with organic salts are very interesting, but more exclusively to the chemist. The oxidizing and reducing actions are very powerful, as the bodies probably act in the "nascent state."

Solutions of acetate and nitrate of lead, when electrolyzed by currents of small density, deposit at the positive electrode hydrated peroxide of lead as a black powder. If a polished iron plate be used as the anode, the deposit shows prismatic colors depending on the thickness, and the process has been applied in the arts to color metallic toys, under the name of metallochromy. If a fine wire as cathode be placed vertically above the anode plate, the colours are arranged in circles long known as Nobili's rings. Similar phenomena are exhibited by salts of bismuth, nickel, cobalt, and manganese, all of which are precipitated as peroxides, usually hydrated (Wernicke, *Pogg. Ann.*, cxli. 109), upon the anode by the action of the oxygen liberated by the passage of electricity. Silver is also thrown down as a black peroxide, together with some oxygen from a solution of sulphate and nitrate, and iron behaves somewhat similarly in an ammoniacal solution of the protoxide in vacuo.

Such secondary actions vary very conspicuously with the density of the current and the temperature. Bunsen (*Pogg. Ann.*, xci.) electrolyzed solution of chronic chloride, and by increasing the current density obtained in succession H, Cr_2O_3, CrO_3, and metallic Cr at the cathode; the reason for this is evidently that with high current densities the supply of ions in any time is greater than can take part in secondary action, and hence some of the original ion is deposited. A rise of temperature favors chemical action, and promotes rapid mixture of the ions with the solution at the same time; so the higher the temperature the greater is the current density required to isolate the ions. From concentrated sulphuric acid, for instance, below 80° only H and O are obtained; between 80° and 90° oxygen is given off at the anode, while at the cathode H and S, due to reduction of H_2SO_4 by hydrogen, appear; above 90° sulphur alone is deposited at the cathode (Warburg, *Pogg. Ann.*, cxxxv. 114).

Mixed electrolytes. Instructive and important cases of secondary action occur when the electric current is made to traverse a mixture of several solutions. Magnus (*Pogg. Ann.*, cii. 23) determined by experiments on dilute $CuSO_4$ solution, in an apparatus with a porous diaphragm of clay, colloid paper, or animal membrane, specially arranged that the lines of flow should be parallel, and the current density therefore uniform, that there was a limiting value of the density above which both copper and hydrogen appeared at the cathode, but below only copper. His results show that this density is independent of length of the electrolyte and material of the electrodes, but varies directly as the size of the electrodes. The specific resistance of the constituents, as well as the relative position of the two ions in the "electro-chemical series" (*vid. inf.*), are of great importance, the electro-negative metal always appearing first.

In order to determine whether the current traversed both electrolytes or only one, Hittorf (*Pogg. Ann.*, ciii. 48), with the apparatus above described (p. 102), electrolyzed mixed solutions of potassium chloride and iodide in different proportions, and arrived at the important conclusion that for all densities the current traversed both electrolytes, as it were in multiple arc (though the resistance of the mixture apparently bears no definite relation to the resistances of its constituents except for some of the haloid salts); but the products liberated depend on the secondary action at the electrode, and hence on the current density. The formation of an envelope of liquid of altered composition would also introduce complications (Smee, *Phil. Mag.*, xxv. 437). Buff, by experimenting on solution of HCL, with a small amount of H_2SO_4, substantially confirms Hittorf's results (*Ann. d. Chem. u. Pharm.*, cv. 156).

These considerations are, of course, especially useful in effecting the deposition of alloys by electrolysis. The possibility of so doing appears to depend upon the composition of the solution employed. An acid solution of Cu and Zn deposits only copper, but the addition of potassium cyanide determines the deposition of brass. Gore (*Electro-metallurgy*, p. 51) points out that, in order to deposit an alloy of two metals, there must be no electric separation when the two metals are in contact with the liquid; if indeed such were the case, a deposit of the two metals, say of Cu and Zn, would immediately act as a CuZn couple (see p. 107), and the electro-negative metal alone would be deposited at the expense of the electro-positive.

Migration of the ions. Although the amount of a salt decomposed by the passage of a given quantity of electricity is the same whether the salt be fused or dissolved in alcohol, water, or other solvent, yet the presence of the solvent produces an important effect upon the electrolyte, which should not be lost sight of in quantitative experiments. The phenomenon is known as the "migration of the ions" (Hittorf), or the "unequal transfer of the ions" (Miller). Suppose, for example, we electrolyze a solution of $CuSO_4$ containing ·16 gramme of salt per cubic centimetre, in a vessel separated by a porous diaphragm into two portions A and B. Let electricity be passed through the solution between platinum electrodes from B to A, until 1·59 grammes of $CuSO_4$ have been decomposed. Then—

(1.) 1·59 g. of $CuSo_4$ has been removed from the solution;
(2.) ·63 g. of Cu has been deposited on the platinum cathode;
(3.) ·16 g. of O has been evolved at the anode, and
·80 g. of SO_3 absorbed there by the water of the solution.

Now, had the electrolyte been a single fused compound, no complication could have arisen; the liquid remaining must still have been homogeneous (except for the presence of the ions near one or other electrode). But when the salt is dissolved, it is important to consider *from what part of the solution the salt has been removed.* Suppose that of the $CuSO_4$ decomposed $\frac{1}{n}$th was taken from the vessel B, and therefore $\frac{n-1}{n}$ths from A. The result of electrolysis may then be exhibited thus (assuming that no diffusion takes place through the diaphragm):—

	In A.	In B.
Before Electrolysis	x g. $CuSO_4$.	y g. $CuSO_4$.
After "	$\left(x-\frac{n-1}{n}1{\cdot}59\right.$ g. $CuSO_4$ + ·63 g. Cu, incluing Cu deposited.	$\left(y-\frac{1}{n}.1{\cdot}59\right)$ g. $CuSO_4$ + ·96 g. SO_4, including oxygen collected.

If the volumes of the two vessels are equal, x and y are of course equal, since the fluid is originally homogeneous.

Hence A will gain $\frac{1}{n}\,{\cdot}63$ g. Cu, and lose $\frac{n-1}{n}\,{\cdot}96$ g. SO_4.

B will lose $\frac{1}{n}\,{\cdot}63$ g. Cu, and gain $\frac{n-1}{n}\,{\cdot}96$ g. SO_4.

We may therefore state the result thus:— For every equivalent of copper deposited upon the cathode the entire gain of copper in the vessel A is $\frac{1}{n}$th equivalent, and the entire gain of SO_4 in B is $\frac{n-1}{n}$ equiv. The experiment shows that the entire gain of copper in A is $\cdot 276 \times \cdot 63$ g., and the gain of SO_4 in B is $\cdot 724 \times \cdot 96$ g.; and hence, for solutions of $CuSO_4$ of that strength, $\frac{1}{n} = \cdot 276$, and consequently $\frac{n-1}{n} = \cdot 724$, so that, of the $CuSO_4$ decomposed, 72·4 per cent is taken from A, and 27·6 per cent from B, and the solution round the cathode is weakened much faster than that round the anode. This will be observable by the depth of the blue color of the solution. If the anode be of copper and be vertically above the cathode, the effect is well seen; for although the total amount of $CuSO_4$ in solution remains constant, the difference of color at the two electrodes is very apparent, and, if the action be continued, strong dark-blue solution drops down in thin streams from the anode through the more dilute (Magnus).

The value of n differs for different salts, and usually for solutions of the same salt of different strengths, though in some cases, as K_2SO_4, KNO_3, NaCl, and KCl, the variations for great difference of concentration are very slight. The following table shows a few of the results obtained by Hittorf, with the apparatus described above, by which errors due to diffusion were avoided. The numbers in the third column indicate what is called above $\frac{n-1}{n}$, *i.e.*, the total excess in equivalents of the anion in the vessel containing the anodes corresponding to a decomposition of one equivalent of salt; or, except in the last few cases, that part of the salt decomposed which is taken from the vessel containing the cathode.

Salt.	No. of cc. of solvent containing one gramme of salt.	$\frac{n-1}{n}$
HCl	2·9	·319
HCl	36·2	·168
HCl	140·9	·171
HCl	2125·9	·210
HBr	8·6	·178
HIO_3	13·3	·102
K_2SO_4	11·8	·500
K_2SO_4	412·8	·498
NaCl	20.7	·634
Fe_2Cl_6	25·25	·600
CdI_2	4·2	1·14
	116·7	·613
CdI_2 in alcohol..	1·1	2·102
	37·2	1·318
ZNI_2 in alcohol.. ...	0·5	2·16

The iodides of zinc and cadmium are anomalous, but it may be supposed that they are decomposed as double salts thus:—

$$2CdI_2 = Cd + (CdI_2 + I_2)\,,$$

or

$$3CdI_2 = Cd + (2\,CdI_2 + I_2)\,.$$

Electro-vection or endosmose.

The total increase in the amount of an ion in one part of a vessel divided by a porous partition is also effected by a mechanical transference of the electrolyte through the pores of the diaphragm, generally in the positive direction of the current, which is very noticeable in cases of electrolytes of high resistance. This was discovered by Reuss in 1807, and observed by Porret soon afterwards; it has been investigated by Wiedemann (*Pogg. Ann.*, lxxxvii. 321), and Quincke (*Pogg. Ann.*, cxiii. 513). The former worked with a porous cell, and estimated the effect either by the quantity of the electrolyte which passed through the wall of the cell, the pressure remaining constant, or by the rise of pressure in the porous cell measured by a mercury manometer. A current of moderate intensity through distilled water caused 17·77 g. of the electrolyte to pass through the diaphragm towards the cathode in a quarter of an hour, and with a 19 per cent. solution of $CuSO_4$, a pressure of 176·5 mm. was observed in the cell containing the cathode, due to the current of a battery of Daniell's cells. Quincke, however, employed, instead of a porous cell, a capillary tube without diaphragm, open at one end, and connected with a reservoir at the other containing one electrode, while the other electrode consisted of one of several pieces of platinum wire, sealed into the tube in various positions. His current was obtained from either a Leyden battery, or 40 to 80 Grove's cells. The two ways of experimenting gave concordant results, and showed that the pressure on the cathode vessel varies as the electro-motive force between the electrodes, and so diminishes with the resistance if the current be kept constant. It is also, in Quincke's apparatus, inversely proportional to the square of the diameter of the tube, and, for tubes of the same sectional area, is greatly increased by increasing the perimeter. The direction of motion is, as stated above, usually towards the cathode, and is immediately reversed on a reversal of the current, and stops when the circuit is broken. The rate of transfer is increased by coating the tube with shellac; it is different for different fluids, and with certain specimens of absolute alcohol, and with turpentine oil, the direction is reversed, unless in the latter case the tube is coated with sulphur, when the direction is as before.

Motion of foreign particles.

Intimately connected with these phenomena is the motion of solid particles contained in fluids of high resistance. Faraday observed the motion of silk threads in water, and Jürgensen made many experiments on the subject with a capillary tube in the form of three sides of a rectangle with bulbs at the two corners which contained the electrodes; in one was a porous diaphragm as well. Quincke (*l.c.*) used a similar apparatus to this, as well as the one described above, and observed by means of a microscope a double motion of particles of starch contained in water subject to the action of an electric machine. Near the sides of the tube the particles moved towards the negative electrode, but in the middle in the opposite direction; on turning the machine more quickly the particles near the sides gradually lost their velocity, and then began to move towards the positive electrode in common with those in the middle. So that it is highly probable that near the sides the particles are in the first instance carried along by the motion of the fluid there, but on increasing the current the friction of the liquid in contact with the tube prevents its velocity increasing so fast as that of the particles in the opposite direction, and ultimately the motion of the particles in that direction becomes apparent. Similar phenomena are observed with many finely divided bodies suspended in water, as gold, copper, graphite, silica, felspar, sulphur, lycopodium, etc., as well as minute drops of liquid, as CS_2 and oil of turpentine, and bubbles of oxygen, marsh gas, etc. All these are urged in water towards the positive electrode, but in oil of turpentine the direction is reversed except in the case of particles of sulphur; the direction is also reversed for silica in carbon disulphide.

Faraday's law for different electrolytes.

Considering now our first equation $W = KE$ established, K being, as stated, dependent only on the nature of the electrolyte, we proceed to examine the constant K and its value for different electrolytes. The primary investigation is due to Faraday, who found that if A and B be two electrolytes, and if a quantity E of electricity decomposes a mass X of A and Y of B, then X and Y are *chemically equivalent*, that is, are the amounts of A and B which would take part in a double decomposition between them. According to this view we have for any electrolyte $W = \mu\varepsilon E$, where μ is the amount of the electrolyte chemically equivalent to 1 gramme of water, and ε is the number of grammes of water decomposed by a unit of electricity, and is called the electro-chemical equivalent of water. This appears to be always true, but the law as usually stated refers to the amounts of the ions separated. The most general statement which the facts allow is the following, known as Faraday's law:—*In any electrolytic decomposition whatever, the mass* w *of one at least (usually of each) of the ions, simple or complex, separated* *by the passage of a quantity of electricity* E, *is chemically equivalent to the amount of hydrogen separated by the same quantity of electricity in a water voltameter, and hence* $w=mhE$, *where* m *is the chemical equivalent of the ion, and* h *the electro-chemical equivalent of hydrogen.*

Since water contains $\frac{1}{9}$th its weight of hydrogen $h=\frac{1}{9}\epsilon$.

Faraday admitted as electrolytes only bodies containing an equal number of equivalents of their components, and accordingly found that the amount of either ion was equivalent to the hydrogen evolved in a voltameter included in the circuit. The seventh series of *Experimental Researches* was devoted to proving this most important law. Two methods were adopted—(1) by collecting and measuring the products of decomposition, a voltameter being included in the circuit, and (2) by introducing an anode with which the anion could combine (as for instance a Pb anode in fused $PbCl_2$, a silver one in fused AgCl), and determining the loss in weight of the anode. By these means the law was proved for simple fused electrolytes, such as the chlorides, etc. Daniell extended it to oxygen salt solutions, and showed that they were decomposed into a metal and a complex ion, this last splitting up into oxygen and an anhydride which united with water to form the corresponding acid, *e.g.*,

$$ZnSO_4=Zn+(SO_3+O).$$

Matteucci and E. Becquerel added a large amount of evidence in defence of the law, which was demonstrated with great accuracy (to $\frac{1}{5}$ per cent.) by Soret (*Ann. de Chim. et de Phys.* [3] xlii. 257) for a series of copper salts; and by Buff for great variations of current strength with silver compounds.

So long as we confine ourselves to normal salts there is little difficulty about the statement of the relation; even with such compounds as the series of phosphates, the double cyanides, etc., which are decomposed as in the following table, the amount of either ion may be considered equivalent to the H of the voltameter.

	Electrolyte.	Anion corresponding to H in voltameter.	Cation.	Observer.
Solution of	Na_3PO_4	$\frac{P_2O_5}{3}+\frac{O}{2}$.[1]	Na.	Hittorf.
	$NaPO_3$	$\frac{P_2O_5}{2}+\frac{O}{2}$.[1]	Na.	Daniell and Miller, *Phil. Trans.*, 1844, p. 1.
	$Na_4P_2O_7$	$\frac{P_2O_5}{4}+\frac{O}{2}$.[1]	Na.	
	Na_2HPO_4	$\left(\frac{P_2O_5}{4}+\frac{H_2O}{4}\right)+\frac{O}{2}$.[1]	Na.	
	$NaHNH_4PO_4$	$\frac{H_2(NH_4)_2P_2O_7}{2}+\frac{O}{2}$.[1]	Na.	
	K_4FeCy_6	$\frac{FeCy_2}{4}+Cy$.	K.	
	$KAgCy_2$	$AgCy+Cy$.[2]	K.	
	$K_2Al_24(SO_4)$	$\frac{1}{3}(Al_23SO_4)+\frac{SO_3}{2}+\frac{O}{2}$.[1]	K.	Hittorf.

Becquerel's modification.

Faraday's law is nearly always true for both ions, but there are, as before stated, examples of elements forming two series of electrolyzable salts, especially when dissolved in water. In these cases the *electro-negative ion* is usually equivalent to the H of the voltameter, or we may consider that the chemical equivalent of the positive ion varies, while that of the negative ion remains unchanged in the different combinations; so that ferric chloride may be regarded as a dichloride with formula $FeCl_2$, where $fe=\frac{2}{3}Fe$; cuprous chloride $cuCl_2$, where $cu=2Cu$, and so on. Considerable confusion, too, arose from the arbitrary numbers for chemical equivalents which formerly obtained, and which caused such compounds as Al_2Cl_6, $SbCl_3$, $AuCl_3$, to appear anomalous, and warranted E. Becquerel (*Ann. de Chim. et de Phys.* [3] t. xi. p. 178) in considering that generally the amount of *electro-negative* ion alone was equivalent to the H of the voltameter.[3] This was borne out by his electrolysis of $2N_2O_4$, $7PbO$, $3H_2O$, and N_2O_4, $2PbO$, H_2O, which gave $\frac{7}{4}$ and $\frac{1}{2}$ an equivalent of Pb at the cathode respectively; but the law as thus modified fails in the case of $K_2Cr_2O_7$, which gives $K+(CrO_3+\frac{1}{2}O)$ both in the melted and dissolved state, and in that of Na_2S_5, which gives $Na+(S_2+\frac{1}{2}S)$, and also for basic acetate of lead.

Electrolysis of solutions in contact.

Faraday's law receives striking confirmation from the electrolysis of several solutions arranged in series in contact with each other by means either of porous septa, asbestos wicks, or siphon tubes. Each liquid then acts as an electrode to the adjacent ones, and so at the junction we have separated the anion of one electrolyte and the cation of the next. These in general unite, and if the resulting compound be insoluble, a precipitate is thrown down. Faraday thus precipitated magnesia from its sulphate by electrolyzing a solution of that salt in contact with water, the current passing from the salt solution to the water. Now, in all cases in which the ions unite at the junction, and do not appear free at all, the amount of the cation of one liquid must be chemically equivalent to that of the anion of the succeeding one, and hence obey Faraday's law. Many of the decompositions and combinations thus effected are very interesting, a list showing in a tabulated form the results of experiments by Hisinger and Berzelius, Davy, Daniell, Miller, and others will be found in Wiedemann (*Galv.*, Bd. i. § 368.) We can only mention one example which is of theoretical importance. If the positive electrode be in solution of iodic acid which is in contact with dilute sulphuric acid containing the cathode, then at the surface of separation there will be formed I and SO_4, or H and SO_4, according as the I observed at the negative electrode in the electrolysis of HIO_3 solution is an ion or due to secondary action. By the union of the two ions at the junction the latter is shown to be the case; therefore iodic acid is electrolyzed as $H_2+(I_2O_5+O)$.

Electro-chemical equivalents.

We gather at once from the truth of Faraday's law that we can assign to each ion an electro-chemical equivalent (which may be referred to as E.C.E.), which will enable us to determine at once the amount of the ion which will be separated by a given quantity of electricity. With the notation already used the E.C.E. of an ion $=\frac{1}{9}m\epsilon$. The value of ϵ—the amount of water decomposed by one C.G.S. electro-magnetic unit of electricity—from experiments of Weber, Joule, Bunsen, Casselmann, and Kohlrausch, is ·00093 gramme (Wied. *Galv.*, Bd. iii. § 1077—1079). The quantity *m* is one of the chemical equivalents of the ion, usually that deduced from its most stable salts; some metals, indeed, with two series of salts have two E.C.E.s. The following table of the elements gives the values of *m* and the E.C.E.s in absolute units, as far as they have been experimentally determined. Since *m* bears a simple ratio to the atomic weight, its value can be corrected by the results of chemical analysis.

Table of Electro-chemical Equivalents.

Element.	Atomic Weight.	Electro-chemical Equivalent in Hydrogen units (m).	E.C.E. in grammes per C.G.S. unit of Elec. $=\frac{1}{9}m\epsilon$.

Every complex ion has also a definite electro-chemical equivalent, usually coinciding with its chemical equivalent. The E.C.E. of an electrolyte is the sum of the E.C.E.s of its component ions.

---

[1] This oxygen is set free.

[2] The well-known deposit of silver in electro-plating is due to secondary action of the K.

[3] The chemical equivalents of Al, Sb, Au were taken to be 13·5, 61, 98 respectively, instead of 9·1, 40·6, 65·5 as now.

[4] Faraday, *Exp. Res.*, ser. vii.

[5] Renault (*l.c. infra.*).

[6] Either these elements have not been obtained as *ions* by electrolytic action, or quantitative experiments are wanting.

[7] Bunsen.

Renault[1] determined the E.C.E.s by an inverse method. He observed the amount of the metal which, forming the negative pole of a battery with various electrolytes, gave a current equivalent to that produced by the dissolution of a definite amount of zinc in a ZnPt cell, the two currents passing through a differential galvanometer, and thus compared the amounts of elements which generate the same quantity of electricity in combining. It is perhaps necessary to observe that the electrolytic reactions taking place in a galvanic cell which generates a current are in every way identical with those due to a current from an external source sent through the electrolyte. In the former case, the energy of chemical affinity at the electrodes is transformed into the energy of electrical separation, and in the latter the converse is the case.

The Electro-chemical Series.

Electro-chemical series.

It is evident from all the examples we have given that it is not an accident whether an ion will appear at the anode or cathode; the cations have been all more or less similar in character, and were either metals or more allied to the metals than the corresponding anions, which were bodies like Cl, Br, I, CN, O, etc. Faraday (*Exp. Res.*, 847) was accordingly led to consider that an element or radicle was unalterably either an anion or a cation; this, however, was contradicted by the fact that the same element may act as an anion in one solution and a cation in another, as is the case with iodine, which in KI is an anion, but from a solution of iodine bromide (IBr) appears at the cathode. The electrolysis of alloys[2] points in the same direction, so that the conclusion is suggested to us that "anion" and "cation" have only relative meanings, and that we might arrange the elements in a series such that, in a compound of an element A with any one of those above it, A would appear as a cation, but in a compound with any of those below, as an anion. To do this by purely electrolytic means is out of the question, as binary electrolytes do not exist for each pair of elements. As far, however, as the series can be thus made out, it is found that, as a rule, if two elements A and B, such that A is above B in the series, be immersed in a simple electrolyte, as dilute H_2SO_4, and connected by means of a wire, the current flows from B to A through the liquid. Hence in unknown cases we may observe the direction of the current when the two elements are immersed in an electrolyte, say H_2SO_4, and determine the relative position in the series.[3] With the series thus roughly formed, it is observed that the wider two elements are apart the greater is the chemical affinity between the two, and thus that if we have a compound MR, where M is the electro-positive element, a more electro-positive element M′ having a greater affinity for R than M tends to replace M from the compound, and a more electro-negative element R′ tends to replace R as iron replaces copper from $CuSO_4$, and chlorine iodine from KI. This further assists us in forming an electro-chemical series of the elements, but it is still not very strictly arranged, and many of the members of the series are placed by their analogy to elements whose positions are known. Moreover, it is supposed that the relative position of two elements may vary with the temperature. Thus carbon, which is used in batteries as the negative element, is at a full red heat electro-positive even to potassium, or at least reduces the carbonate of that element. Jablochkoff (*Comptes Rendus*, Dec. 3, 1877) describes a cell of which the positive element is coke. The electrolyte is fused sodium or potassium nitrate, and the negative element is a cast-iron vessel containing the fused salt. The current is from coke to cast iron through the nitrate, and the electro-motive force 2 to 3 volts.

Berzelius's final series stands thus:—

Electro-negative.

Oxygen.	Boron.	Mercury.	Thorium.
Sulphur.	Carbon.	Silver.	Zirconium.
Selenium.	Antimony.	Copper.	Aluminium.
Nitrogen.	Tellurium.	Bismuth.	Didymium.
Fluorine.	Tantalum.	Tin.	Lanthanum.
Chlorine.	Titanium.	Lead.	Yttrium.
Bromine.	Silicon.	Cadmium.	Glucinum.
Iodine.	Hydrogen.	Cobalt.	Magnesium.
Phosphorus.	Gold.	Nickel.	Calcium.
Arsenic.	Osmium.	Iron.	Strontium.
Chromium.	Indium.	Zinc.	Barium.
Vanadium.	Platinum.	Manganese.	Lithium.
Molybdenum.	Rhodium.	Uranium.	Sodium.
Tungsten.	Palladium.	Cerium.	Potassium.

Electro-positive.

Radicles as NH_4 and SO_4 behave as elements, and have each a definite position in the series.

Theory of Electrolysis.

Hypothesis of Grotthuss.

Any hypothesis which seeks to account for the phenomena of electrolysis has mainly to deal with the two points—(1) that the ions appear only at the electrodes, and (2) that the electricity at the same time is conducted between the electrodes. From the behavior of electrolytes in contact on the passage of the current we conclude that if we had a series of cells consisting alternately of KCl and NaCl, the result of electrolysis might be represented thus:—

Before electrolysis,

$$\text{KCl,NaCl,KCl,NaCl};$$

after it,

$$-\text{K NaCl,KCl,NaCl,Cl}+.$$

Now, we may suppose similar effects to occur if the cells were all identical, and farther we may consider the collection of molecules in any electrolyte as such a series of cells in contact, and argue the electrolytic process to be a series of decompositions and recombinations along a line of molecules resulting finally in the decomposition of molecules at the electrodes alone. The decomposition of any oxygen salt would be similar, with the exception that the one ion is complex. Thus

$$-\text{Zn}\overbrace{\text{SO}_4,\ \text{Zn}}\overbrace{\text{SO}_4,\ \text{Zn}}\text{SO}_4+$$

might represent the decomposition of zinc sulphate. This idea of alternate decompositions and recombinations was originally suggested by Grotthuss in 1805, who, however, attributed the separation to attractions, due to the electrodes, varying inversely as the square of the distance. Faraday (*Exp. Res.*, 481–563, series iv.) discusses the theory, and, while denying the attractions of the electrodes, defends the idea of decomposition and reformation, chiefly against De la Rive and Riffault and Chompré, and considers that the effect of the passage of the current is due to a change of the chemical affinities of the components of the electrolyte, and he points out (1343 *sqq.*, ser. viii.) that the decomposition is probably preceded by a polarized state of the particles, as explained by him in his theory of electro-static induction. This is confirmed by experiments of Tribe (*Proc. Roy. Soc.*, 1875–6), who inserted 198 small strips of silver in rows, parallel to the line joining the electrodes in dilute $CuSO_4$, and observed that copper was deposited on the ends facing the anode, while gas was given off from the other ends; by comparing the amounts of the deposit he explored the electric field, showing that it was roughly similar to the magnetic field due to a north and a south pole.

Hittorf's theory.

Many investigators have suggested additions to Grotthuss's hypothesis (see Wiedemann, i. 421, *a*.), and in particular Hittorf (*Pogg. Ann.*, lxxxix.) has expanded it to explain the migration of the ions in salt solutions investigated by him. He supposes that the molecules are equal distances apart, and that the ions when separated travel with different velocities to the points of recombination, and consequently those points are not the middle points between pairs of adjacent molecules. He thus considers that the cation travels $\frac{1}{n}$th of the distance between molecules while the anion travels $\left(1-\frac{1}{n}\right)$th of the distance.

If then we suppose the ions separated at the electrodes to be removed, we may imagine the positions of the particles *in the medium of solution* before and after electrolysis to be represented by a. . . . . a'. . . . . respectively, thus (where $n=4$):—

$$\begin{array}{c|ccccccccccccccccccccc|c} - & a & & a & & a & & a & & a & & a & & a & & a & & a & & a & & a & + \\ & & a' & & a' & & a' & & a' & & a' & & a' & & a' & & a' & & a' & & a' & & \end{array}$$

the effect will be the same as if (1) the particle nearest the negative electrode were removed, and all the other particles in the line moved towards that electrode $\frac{1}{n}$th of the distance between the particles, or as if (2) the particle at the positive electrode were removed, and all the rest shifted $\left(1-\frac{1}{n}\right)$th part of the distance between the particles towards it. If we suppose the solvent separated by a porous wall into two portions, we shall have after electrolysis in the portion containing the cathode (on the first supposition) corresponding to deposition of one equivalent of hydrogen in the voltameter—

(1) a gain of one equivalent of cation deposited;
(2) a loss of one equivalent of salt, since the decomposed molecules are supposed taken from there;

---

[1] "Vérification expérimentale de la réciproque de la loi de Faraday, sur la décomposition des électrolytes," Paris, 1867; *Ann. de Chim.* [4] xi. 137.

[2] Alloys of tin and lead, potassium and sodium, sodium amalgam, gold amalgam, and fused cast iron have all been shown to suffer chemical decomposition on the passage of the electric current (Wied. *Galv.*, i. § 328).

[3] This is not always conclusive evidence, as the direction of the current for the same two elements sometimes varies with the electrolyte employed, as will be seen by referring to the list of chemico-electric series in Gore, *Electro-metallurgy*, p. 66. The boracic acid series is peculiarly anomalous.

(3) a gain of $\frac{1}{n}$ equivalent of salt due to translation.

Hence the whole increase in the amount of the cation, free and combined, due to electrolysis is $\frac{1}{n}$ equivalent.

In the portion containing the anode we shall have—(1) a gain of one equivalent of anion set free, and (2) a loss of $\frac{1}{n}$ equivalent of electrolyte due to the translation; and hence the whole increase in the amount of anion free and combined round the anode is $\left(1-\frac{1}{n}\right)$ equivalent. The same results are obtained if the second supposition be made. Hence the n here used is identical with the n used above in the account of the phenomena of migration of the ions. D'Almeida considered that the phenomena were due to the fact that round the positive electrode an envelope of free acid was formed by electrolysis, and that this became a second electrolyte in contact with the salt solution. It is also evident that by supposing the salt to be electrolyzed in a hydrated state, *i.e.* combined with a number of molecules of water which may travel with either the anion or cation, an explanation of the phenomena may be arrived at (Burgoin, *Bull. Soc. Chim.* [2] xvii. 244). Hittorf explained the remarkable cases of the iodides of zinc and cadmium by a somewhat similar assumption (*v. supra*, p. 103).

Extension by Kohlrausch.

F. Kohlrausch (*Nacht. v. d. K. Ges. d. Wiss.*, Göttingen, 17 Mai, 1876, 4 April, 1877) has recently pointed out a most remarkable relation between the migration constants and the conductivities of extremely dilute solutions containing *electro-chemically equivalent amounts* of haloid or oxygen salts. Thus if l_1, l_2 be the conductivities of such solutions of two salts MR, MR′ containing one component M the same in both, and if n_1, n_2 be the corresponding migration constants of the ion M, then Kohlrausch shows that the equation $\frac{l_1}{l_2}=\frac{n_2}{n_1}$ holds with remarkable accuracy for many salts. The quantities l_1, l_2 are called the "specific molecular conductivities" of the solutions, and are defined by the equation $l=\frac{k}{\mu}$, where $\frac{k}{10^7}$ is the specific conductivity of a very dilute solution at 18° C. referred to mercury, and μ is the ratio of the number of grammes of salt per unit of volume of solution to its electro-chemical equivalent in hydrogen units. The results are in accordance with the hypothesis that the conductivity of an electrolyte is proportional to the sum of the oppositely directed velocities of the anion and cation; the velocity of any ion is supposed to depend on the friction of the surrounding fluid, and is accordingly constant for the same ion in different solutions if these are extremely dilute. A table of relative velocities can be formed from the migration constants of Hittorf, Wiedemann, and Weiske; a multiple of these velocities gives numbers such that the sum of those corresponding to two ions gives a value for the molecular conductivity of a solution of the compound of the two ions agreeing very closely with the experimental determinations of Kohlrausch and Grotrian.

Hypothesis of conduction.

In order to explain the conduction of electricity during electrolysis several hypotheses have been suggested, which involve the idea of continuity of electricity, even in the molecules. On this view the elementary atoms when recombining carry with them a certain quantity of electricity, which, indeed, by Faraday's law, must be the same for every group of atoms constituting a chemical equivalent. Berzelius, for example, considers that when two atoms, *e.g.*, H and Cl, unite to form HCl, electric distribution takes place similar to that of magnetism in a bar magnet, H being the positive pole, Cl the negative. The hypothetical positive pole is then attracted by the negative electrode, and the attraction is so great at the electrode itself as to overcome the chemical affinity of the H for Cl, and separation is the result, while the electricity of the electrode and of the H combine and are neutralized. The liberated chlorine atom then behaves in the same way towards its next neighbor, and so the current of electricity is set up.

Hypothesis of Clausius.

For an account of the allied theories see Wiedemann, *l.c.*, and see also Clerk Maxwell's remarks upon the subject (*Elec. Mag.*, vol. i. § 259 *sqq.*). These hypotheses nearly all involve the idea, more or less defined, of a statical molecule, *i.e.*, a molecule at rest relatively to other molecules, and consisting of relatively fixed atoms; but while we regard heat as the energy of molecular motion, this notion of a molecule cannot be sustained, and accordingly the above hypothesis can serve, as Maxwell suggests, merely to give precision to our ideas. Clausius (*Pogg. Ann.*, ci. 338), however, has applied the kinetic hypothesis of the constitution of bodies to electrolysis, and from his suggestions we can form some conception of the method of proceeding in electrolytic action. He supposes the molecules in the ordinary state to be in a state of agitation, and the atoms composing the molecules to be also in motion, sometimes separating, sometimes recombining with other separated atoms, so that decomposition and recombinations are continually going on, but in no definite direction. The mean result is an apparent state of equilibrium. When, however, an electro-motive force acts upon the electrolyte, no matter how small it is, it causes the atoms, when liberated as usual, to tend in one direction, viz., along the lines of force. Hence the collection of the ions at the electrodes, where they will separate if the electro-motive force be sufficient to prevent them reacting and again recombining,—in other words, sufficient to bear the polarization. This, though by no means a complete theory, is indeed applicable to ultimate atoms, and is the only one which admits decomposition for all electro-motive forces. Clausius shows that the finite electro-motive force is necessary to *maintain the ions in the free state* at the electrodes.

Quincke's theory.

One theory, which we must mention because it accounts at once for conduction, the migration of the ions, and "electric endosmose," is that due to Quincke (*Pogg. Ann.*, cxiii., extended in cxliv.), who considers the ions of each molecule charged with quantities of electricity ϵ and ϵ'; then the force K tending to separate the ions from each other $=-\frac{dv}{dx}(\mathrm{B}\epsilon-\mathrm{B}'\epsilon')$, where B and B′ are constants, and $\frac{dv}{dx}$ is the electro-motive force per unit of length of the electrolyte, and is consequently $=-\frac{i}{qk}$, where i is the current intensity, q the sectional area of the electrolyte, and k its specific conductivity; so that $k=\frac{i}{qk}(\mathrm{B}\epsilon-\mathrm{B}'\epsilon')$, and electrolysis takes place when this is greater than the force of chemical affinity. This is a weak point of the theory, as a finite electro-motive force would be required to produce any decomposition or polarization.

The forces on the ions when separated, and hence their respective velocities, will be proportional to ϵ and ϵ'. This will account for the migration of the ions, for which ϵ and ϵ' are supposed unequal and of different signs in all cases except ZnI and CdI, etc., for which $\left(1-\frac{1}{n}\right)$ is greater than unity; for these ϵ and ϵ' may be of the same sign. If, on the other hand, ϵ be the amount of free electricity on a molecule of the electrolyte (supposed of high resistance) in contact with the glass, then $-\mathrm{B}\frac{dv}{dx}\epsilon$ will represent the force urging the fluid in the positive direction of the current, and perhaps producing endosmose, since ϵ will be positive except for turpentine oil. So the motion of particles may be similarly explained by supposing ϵ to be the charge on them due to contact with the fluid; this is negative with particles in water, and positive for all particles except sulphur in turpentine oil. The results thus obtained will be found to agree closely with the experiments mentioned above (p. 104); and the quantitative results also agree, since the force on a particle equals $\mathrm{B}\frac{i}{qk}\epsilon$, and therefore varies as the current density i, and inversely as the conductivity k.

Zinc copper couple.

An application of electrolysis, which has already proved to be of great value in chemistry, has been introduced of late years by Gladstone and Tribe. In a paper read before the British Association in 1872 (*Trans. of Sections*, p. 75, see *Proc. Roy. Soc.*, vol. xx. p. 218) they showed that although zinc alone does not decompose distilled water, yet if zinc foil be immersed in dilute solution of cupric sulphate, and be thereby coated with metallic copper, which is thrown down as a black crystalline powder, containing traces of zinc only if the time of immersion be very long (*Journal Chem. Soc.*, 1873, p. 452), and if the zinc copper couple thus produced be immersed in distilled water at ordinary temperature, about 4 cc. of H can be collected per hour. The hydrogen is seen by the microscope to collect upon the copper crystals, while the zinc is oxidized, and forms a hydrate. The rate of evolution of hydrogen varies with the temperature; the relation may be exhibited by a curve very similar to the curve of tension of water vapor. Gladstone and Tribe have found this a powerful method of acting upon many organic bodies, particularly the halogen compounds of the alcohol radicles. In all cases either new reactions were set up, or the temperature at which reaction takes place was very much lower than with ordinary zinc (see the series of papers by Gladstone and Tribe in the *Jour. Chem. Soc.*, 1873–76). To the chemist the ZnCu couple affords an exceedingly convenient way of arranging electrolysis, since the whole may be contained in one vessel. For the copper in the arrangement, gold or platinum may with great advantage be substituted by immersing zinc foil in solutions of the chlorides.

This easily explains the well-known custom of generating hydrogen from zinc and sulphuric acid, to which a little $CuSO_4$

is added; and the "local action" in batteries, when currents pass from one part to the other of the same mass of metal and consequently energy is expended for which no external equivalent is obtained, may be similarly referred to the difference of composition of the metals in the two places. It should be remembered that Davy suggested the preservation of the copper sheathing of ships by attaching plates of Zn; the same object is now achieved by using an alloy of the two metals.

The application of the principle of the conservation of energy to electrolysis has already produced valuable results; research, however, in this direction is rendered difficult on account of the great number of circumstances which have to be taken into account, in computing the balance of energy expended and work done; the chemical composition and physical state of the electrolyte, the molecular condition of the ions, and the secondary actions at the electrodes have all to be taken into account. For a notice of the present state of this branch of the subject the reader is referred to the article Electricity. (W. N. S.)

ELECTRO-METALLURGY, a term introduced by the late Mr. Alfred Smee to include all processes in which electricity is applied to the working of metals. It is far more appropriate than the French equivalent *galvano-plastie*, or the German *Galvano-plastik*, since the metals are certainly not rendered plastic under galvanic action, though it is true that in electrotypy, which forms one branch of electro-metallurgy, the metal is deposited in moulds, and can thus be used to reproduce works of plastic art.

It was observed as far back as the beginning of the present century that certain metals could be "revived" from solutions of their salts on the passage of a current of electricity. The germ of the art of electro-metallurgy may undoubtedly be traced to the early experiments of Wollaston, Cruickshank, Brugnatelli, and Davy; but it remained undeveloped until the late Professor Daniell devised that particular form of battery which bears his name, and which he described in the *Philosophical Transactions* for 1836. A Daniell's cell consists, in its usual form, of a copper vessel containing a saturated solution of blue vitriol or sulphate of copper, in which is placed a porous cylinder containing dilute sulphuric acid; a rod of amalgamated zinc is immersed in the acid, and on the two metals being connected by means of a conductor, electrical action is immediately set up. The zinc, which forms the positive or generating element, is dissolved, with formation of sulphate of zinc; whilst the blue vitriol is reduced, and its copper deposited, in metallic form, upon the surface of the copper containing vessel, which forms the negative or conducting element of the combination. Any one using this form of battery can hardly fail to observe that the copper which is thus deposited takes the exact shape of the surface on which it is thrown down, and indeed presents a faithful counterpart of even the slightest scratch or indentation. Mr. De la Rue incidentally called attention to this fact in a paper published in the *Philosophical Magazine* in 1836, but it does not appear that any practical application was at the time suggested by this observation. Indeed, the earliest notice of electro-metallurgy as an art came from abroad two or three years later.

Sturgeon's *Annals of Electricity* for March, 1839, contained a letter from Mr. Guggsworth, announcing that Professor Jacobi, of St. Petersburg, had recently discovered a means of producing copies of engraved copper plates by the agency of electricity. This was the first news of the new art which appeared in England, and it evidently referred to the paper which Jacobi communicated to the St. Petersburg Academy of Sciences on October 5, 1838, and in which he explained his process. In the *Athenæum* of May 4, 1839, there was a short paragraph relating to Jacobi's discovery, and public attention in this country was thus drawn to the subject. Only four days after the appearance of this paragraph, Mr. Thomas Spencer, of Liverpool, gave notice to the local Polytechnic Society that he would read a paper on a similar discovery of his own. This paper was not read, however, until September 13; and although the author wished to describe his process before the British Association at Birmingham in August, it appears that his communication was never brought before the meeting. In Mr. Spencer's paper, which was eventually published by the Liverpool Polytechnic, he states that his attention was first directed to the subject by mere accident: he had used a copper coin, instead of a plain piece of copper, in a modification of Daniell's cell, and on removing the deposited metal he was struck with the faithful copy of the coin which it presented, though of course the copy was in intaglio instead of relief. Yet even this observation was allowed to remain unproductive until another accident called his attention to it afresh. Some varnish having been spilt upon the copper element of a Daniell's cell, it was found that no copper was thrown down upon the surface thus protected by a non-conducting medium; hence it was obvious that the experimentalist had it in his power to direct the deposition of the metal as he pleased; and this led Mr. Spencer to prosecute a series of experiments by which he was at length able to obtain exact copies of medals, engraved copper plates, and similar objects. It should be mentioned that between the date on which he announced his paper and the date on which it was actually read, Mr. C. J. Jordan, a printer, described experiments which he had made in the preceding year very similar to those of Spencer. This announcement was made in a letter published in the London *Mechanics' Magazine* for June 8, 1839. It thus appears that three experimentalists were close upon the same track about the same time, but it is generally admitted that among these competitors Mr. Spencer has the merit of having been the earliest to bring his process to perfection, and to demonstrate its practical value.

Soon after the appearance of Mr. Spencer's paper, it became a fashionable amusement to copy coins, seals, and medals by the new process. These copies in metal are termed *electrotypes*. The apparatus employed in the early days of the art, and which may still be conveniently used for small electrotypes, is similar in principle to a single Daniell's cell. It usually consists of a glazed earthenware jar containing a solution of sulphate of copper, which is kept saturated by having crystals of the salt lodged on a perforated shelf, so that they dip just below the surface of the solution. A smaller porous cylinder, containing very dilute sulphuric acid, in which a rod of amalgamated zinc is placed, stands in the jar, and is therefore surrounded by the solution of sulphate of copper. The object to be copied is attached by a copper wire to the zinc, and is immersed in the cupric solution. It thus forms the negative element of a galvanic couple, and a current of electricity passes from the zinc through the two liquids and the intervening porous partition to the object, and thence back to the zinc through the wire, thus completing the circuit. During this action, the zinc dissolves, and sulphate of zinc is formed; at the same time the copper solution is decomposed, and its copper deposited upon the metallic surface of the object to be coated,—the solution thus becoming weaker as it loses its copper, but having its strength renewed by consumption of fresh crystals of blue vitriol. To avoid the complete incrustation of the metal or other object, one side of it is coated with varnish or some other protective medium, so that the deposition of copper takes place only on such parts as are exposed. The deposit may be easily removed when sufficiently thick, and will be found to present an exact counterpart of the original, every raised line being represented by a corresponding depression. To obtain a fac-simile of the original it is therefore necessary to treat this matrix in the same way that the original was treated, and this second deposit will of course present the natural relief. Another method consists in taking a mould of the original coin in fusible metal, and then depositing copper upon this die, so as to obtain at once a direct copy of the original.

Considerable extension was given to the process by a discovery, apparently trivial, which was first announced by Mr. Murray at a meeting of the Royal Institution in January, 1840. He found that an electro-deposit of metal could be formed upon almost any material if its surface was rendered a conductor of electricity by a thin coating of graphite or "black-lead." Instead, therefore, of copying a coin in fusible metal, or indeed in any metallic medium, it is simply necessary to take a cast in plaster of Paris, wax, gutta-percha, or other convenient material, and then to coat the surface with finely powdered black-lead, applied with a camel-hair pencil. Medals in high relief, with much undercutting, or busts and statuettes, may be copied in electrotype by first taking moulds in a mixture of glue and treacle, which forms an elastic composition capable of stretching sufficiently to permit of removal from the object, but afterwards regaining its original shape.

About the same time that Murray suggested the use of black-lead, Mr. Mason made a great step in the art by introducing the use of a separate battery. Daniell's cell, in consequence of its regular and constant action, is the favorite form of electric generator. The copper cylinder of this arrangement is connected with a plate of copper placed in a trough containing a solution of sulphate of copper, to which a small quantity of free sulphuric acid is commonly added; whilst the zinc rod of the cell is connected with the objects on which the copper is to be deposited, and which are also suspended in the bath of cupric solution. The current enters the bath at the surface of the copper plate, which is the *anode* or positive pole of the combination, and passes through the solution to the suspended medals which constitute the *cathode* or negative pole. As fast as the copper is thrown down upon these objects, and the solution is therefore impoverished, a fresh supply is obtained by solution of the copper plate; this copper is consequently dissolved just as quickly as the electrotypes are produced, and no supply of crystals is needed, as in the case of the Daniell cell. The great advantage of using a separate battery is that several objects may be coated at the same time, since it is only necessary to attach them to a metal rod in connection with the battery. Almost any form of galvanic arrangement may be employed by the metallurgist as a generator of electricity. But as the exciting liquid in a battery needs to be replenished from time to time, and as the zinc plates also wear out, its use is attended with more or less inconvenience in the workshop, and the electro-metallurgist has therefore turned his attention to other sources of electricity. Indeed, as far back as 1842, when the art was but in its infancy, a patent was taken out by Mr. J. S. Woolwich for the use of a magneto-electrical apparatus; and of late years powerful machines in which electricity is excited by means of magnetism have been introduced into electro-metallurgical establishments. When a bar of soft iron, surrounded by a coil of insulated copper wire, is rotated between the poles of a magnet, a current of electricity is induced in the coil at every magnetization and demagnetization of the core. By means of a commutator, these alternating currents in opposite directions may be converted into a constant stream, of electricity, available for the deposition of metals by electrolysis. The armatures are rotated by mechanical means, such as the use of a steam engine, and hence the electricity is ultimately produced by conversion of mechanical work.

In the machine constructed by Mr. Wilde, which has been largely employed by electro-metallurgists, a small magneto-electric apparatus, with permanent magnet, is employed to excite the electro-magnet of a much larger machine. The induced current of the second machine is stronger than that of the first in proportion as the electro-magnet is more powerful than the permanent magnet; this second current may then be used to excite another electro-magnet, and hence by means of this principle of accumulation, currents of great energy may be obtained. The armatures in these machines are constructed on Siemens's principle, and consist of long bars of iron magnetized transversely, and having the wire wound longitudinally. During the rotation of the armature, so much heat is developed that special means are taken to prevent its accumulation. In another form of Wilde's machine, a vertical disc carrying a number of coils, each with its own core, is caused to rotate between two rings of magnets. A powerful machine, with multiple armatures of this kind, is used by Messrs. Elkington at Birmingham, and is capable of depositing 4½ cwt. of copper every 24 hours.

Another recent modification of the magneto-electric machine used by electro-metallurgists is that invented by M. Gramme. A ring of soft iron carrying a large number of coils of insulated copper wire is caused to rotate between the poles of a fixed horse-shoe magnet, and the currents induced in the coils are collected by two metallic discs, whence they may be drawn off for use in electro-deposition. As the core is circular, the magnetization proceeds continuously, and hence the current is uniform; but as both poles of the magnet are used, two opposite continuous currents are simultaneously produced.

Thermo-electricity is another source of electro-motive power of which the practical worker has availed himself. In 1843 a patent was taken out by Moses Poole for the use of a thermo-electric pile in place of a voltaic battery, but it is only within the last few years that such a source of electricity has been introduced into the workshop. The best-known form of thermopile is that devised by M. Clamond of Paris. One element is formed of tinned sheet iron, and the other of an alloy composed of two parts of zinc to one of antimony. A large number of these pairs, insulated from each other, are arranged in circular piles around a central cavity, in which their junctions are heated by means of a Bunsen burner. The ease with which such an apparatus can be manipulated recommends this source of electricity to the electro-metallurgist.

Having procured a supply of electricity from one or other of these sources, the electro-metallurgist applies it either to the deposition of a metal upon a matrix or to the coating of one metal by another. Hence the art of electro-metallurgy divides itself into two branches, one being called *electrotypy*, and the other being generally known as *electro-plating*. In an electrotype the reduced metal is separated from the mould on which it is deposited, and forms a distinct work of art; whilst in electro-plating the deposited metal forms an inseparable part of the plated object.

It has already been explained how electrotypes are generally taken. One of the most important branches of this art is that of producing copper duplicates of engravings on wood. A cast of the block is first taken in wax or in gutta-percha, and when cold the surface of this mould is brushed over with black-lead; by means of a wire, the black-leaded mould is suspended in a bath of sulphate of copper connected with a battery, and in the course of a few hours a sufficiently thick plate of copper is deposited. The copy, on removal from the mould, is strengthened by being backed with type-metal; it is then planed smooth at the back, and mounted for use on a wooden block. This process is now carried out on a large scale, since it is found that a greater number of sharp impressions can be obtained from the electro than from the wood. For rotary printing machines the electrotypes are curved. Set-up type is also sometimes copied thus instead of being stereotyped, the electro-deposited copper being harder than the stereo metal.

Copper is sometimes thrown down as a thin coating upon plaster busts and statuettes, thus giving them the appearance of solid metal. In Paris, too, it is now common to give a thin coat of electro-deposited copper to exposed iron-work, such as gas-lamps, railings, and fountains. The iron is first painted, then black-leaded, afterwards electro-coppered, and finally bronzed. Cast-iron cylinders used in calico-printing are also coated with copper by a single-cell arrangement; and it has been suggested to coat iron ships in a similar manner. Usually, however, the electro-plater has to cover the baser metals with either silver or gold.

Electro-plating was introduced very soon after the discovery of the art of electro-metallurgy, the earliest investigators being Messrs. G. R. and H. Elkington, Mr. Alexander Parkes, and Mr. John Wright in this country, and M. de Ruolz in France. It was Mr. Wright who first employed a solution of cyanide of silver in cyanide of potassium, and this is the solution still in common use. It should be borne in mind that the cyanide of potassium is a very dangerous poison. The objects to be silver-plated are usually made of German silver, which is an alloy of copper, zinc, and nickel. Before being placed in the depositing vat, the articles must be thoroughly cleansed. Grease is removed by a hot solution of caustic potash, and mechanical cleaning is commonly effected by means of a bundle of fine brass wires, known as a "scratch-brush;" the brush is mounted on a lathe, so as to revolve rapidly, and is kept moist with stale beer. Articles of copper, brass, and German silver are usually prepared by being dipped in different kinds of "pickle," or baths of nitric and other acids. To insure perfect adhesion of the coating of silver, it is usual to deposit a thin film of quicksilver on the surface, an operation which is called "quicking." The quicking liquid may be a solution of either nitrate or cyanide of mercury. After being quicked, the articles are rinsed with water, and then transferred to the silver-bath, where they remain until the deposit is sufficiently thick. The quantity of silver must depend upon the quality of the article: one ounce of silver per square foot forms an excellent coating, but some electro-plated household goods are turned out so cheap that they must carry but the merest film of silver. The vats in which the electro-plating goes on were formerly made of wood, but are now usually of wrought iron. Plates of silver are suspended from a rectangular frame connected with the positive pole, whilst the articles to be plated are suspended by wires from a similar smaller frame communicating with the negative pole. Large articles are suspended from wires, looped at the end, and protected in tubes of glass or india-rubber, whilst small articles may be placed in wire cages or in perforated stoneware bowls. On removal from the depositing vat, the plated objects are usually dipped in hot water, then scratch-brushed with beer, again washed with hot water, and finally dried in hot sawdust. A bright silver surface, requiring no further treatment when removed, may be obtained by adding to the silver bath a very small proportion of bisulphide of carbon.

Electro-gilding is effected in much the same way as electro-silvering. It is found, however, that magneto-electricity cannot be employed with advantage. Various gilding solutions are in use, but preference is usually given to the double cyanide of gold and potassium, originally introduced by Messrs. Elkington. The solution is generally used hot, its temperature ranging from 130° Fahr. to the boiling-point. If the object to be gilt is not of copper, it is usual to coat it with an electro-deposit of copper before submitting it to the gilding solution. The coating of gold is generally very thin, and only a few minutes' exposure to the hot solution is necessary to effect its deposition. When the solution is fresh, a copper anode may be employed, its place being taken by a small gold electrode after the solution has been in work for some time. The presence of copper in the solution imparts a full reddish color to the electro-deposit of gold; and the tone of the metal may also be modified by the presence of salts of various other metals, such as those of silver. Sometimes only part of an object is to be gilt, such as the inside of a silver-plated cream-jug; in this case the vessel would be filled with the gilding solution, in which the anode of the battery is immersed. Gold is sometimes deposited not as a coating upon other metals, but as an electrotype in gutta-percha or in plaster moulds; small objects of elaborate workmanship being thus produced in solid gold, without the workmanship of the chaser and engraver.

Although copper, silver, and gold are the metals to which the attention of the electro-metallurgist is usually restricted, it should be remembered that he is also able to obtain electro-deposits of a very large number of other metals. Many of these are not practically used, but one of them has of late years become of considerable importance. This is the metal *nickel.* In 1869 Dr. Isaac Adams of Boston, United States, patented a process for depositing nickel from solutions of various double salts; but Dr. Gore had many years previously employed similar salts in England, and had published the results of his experiments. The deposition of nickel, especially from the sulphate of nickel and ammonium, is now carried out on a large scale both in England and in the United States. The metal is deposited as a very thin but excessively hard coating, and has the advantage of not readily tarnishing or corroding even in a moist atmosphere. Hence it has become common to electro-nickel iron and steel objects for use on board ship, as well as gun-barrels, sword-scabbards, harness furniture, gas-burners, and various articles for household use.

Iron, like nickel, may be deposited from its double salts, and excellent results have been obtained by Klein, of St. Petersburg, with the double sulphate of iron and ammonium. Engraved copper-plates are much harder when faced with electro-deposited iron than when unprotected, and they consequently yield a much larger number of impressions before losing their sharpness. Plates for printing bank-notes have been treated in this way.

Not only can the electro-metallurgist deposit simple metals, such as those noticed above, but he is able likewise to deposit certain *alloys,* such as brass, bronze, and German silver. The processes by which this can be effected are not, however, very generally used.

Among the minor applications of electro-metallurgy we may mention the process of electrotyping flowers, insects, and other delicate natural objects. These are first dipped for a moment in a warm solution of nitrate of silver in alcohol, and then exposed to a reducing liquid, such as a solution of phosphorus in bisulphide of carbon; an electro-deposit may then be thrown down upon this metallized surface. Daguerreotypes are sometimes improved by coating them with a very delicate film of electro-deposited gold. Again, in some of the modern photographic processes for printing, copper electrotypes are taken directly or indirectly from the bichromatized gelatine. Of late years, too, a method of refining crude copper by means of electro-metallurgy has been introduced, and is now successfully carried out on a large scale. Slabs of blister-copper are plunged into a solution of sulphate of copper, and form the anodes of a battery; the copper then dissolves, and is deposited in a condition of great purity at the opposite pole, most of the impurities sinking to the bottom of the depositing vat. The process should be restricted to copper which is free from any metals likely to be deposited along with the metal under purification.

It has been considered desirable not to include within the limits of this article any of the numerous formulæ for preparing the solutions used by electro-metallurgists. For these, and for other details, see the treatises of G. Gore (1877), J. Napier (5th ed., 1876), A. Watt (5th ed., 1874), A. Smee (3d ed., 1851), and G. Shaw (1844); C. V. Walker's *Electrotype Manipulation* (1850); and H. Dirck's *History of Electro-metallurgy* (1863).

(F. W. R.*)

Definition of terms.

ELECTROMETER. An electrometer, according to Sir Wm. Thomson, who is the greatest living authority on this subject, and has done more than any one else to perfect this kind of physical apparatus, is "an instrument for measuring differences of electric potential between two conductors through the effects of *electro-static* force." A galvanometer, on the other hand, which might also be defined as an instrument for measuring differences of electric potential, utilizes the *electro-magnetic* forces due to the currents produced by differences of electric potential. An instrument designed merely to *indicate,* without measuring, differences of electric potential is called an *electroscope.* It is obvious that every electrometer may be used as an electroscope, and it is also true that all electroscopes are electrometers more or less; but the name electrometer is reserved for such instruments as have a scale enabling us, either directly or by appropriate reduction, to refer differences of potential to some unit.

The modern electrician is far more concerned with measurements of electric potential than with measurements of electric quantity; and consequently all modern electrometric instruments are suited for direct measurements of the former kind. It is only indirectly that such instruments measure electric quantity. With the older electricians it was otherwise; and some of the earliest electrometers were designed for the direct measurement of quantity.

Lane's jar.

Such was the measuring jar of Lane,[1] represented in fig. 1 (after Riess). D is a Leyden jar, fastened to a stand in such a way that its outer armature can be insulated or connected to earth at will. The inner armature is in good metallic connection with the knob C. A horizontal metal piece A is mounted on a glass pillar, and carries another knob, which can be set at any required distance from C by means of a screw and graduation. The piece A is connected with the outer armature of the jar by a thin wire B contained in a glass tube. This last piece was added by Riess,[2] whose arrangement of the apparatus we have been describing. One way of using the instrument is as follows. The balls are set at a convenient distance apart, the stand is carefully insulated, and the outer armature of the jar connected with the battery of jars or other system to be charged, and the inner armature with the source of electricity, say the prime conductor of an electric machine. The electricity accumulates on the inner armature till a certain difference of potential between C and A is reached, and then a certain quantity q of electricity passes from C to A in the form of a spark, after which a quantity q remains distributed between the outer armature and the accumulator which is being charged. This pro-

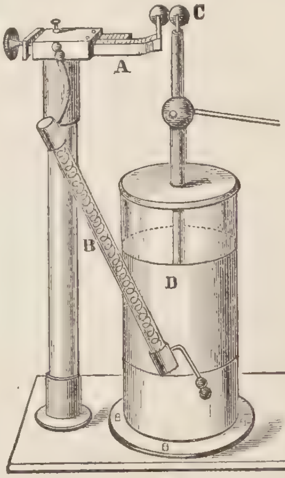

Fig. 1.—Lane's Jar.

[1] *Phil. Trans.*, 1769.

[2] The object of the fine wire is to absorb the energy of the discharges, and prevent the disintegration of the metal of the balls which renders the action of the apparatus irregular (see Riess, *Reibungselectricität*, § 386).

cess is continued, and as each spark passes, a quantity q is added to the charge on the outer armature and accumulator. Hence if the capacity of the outer armature be negligible compared with that of the accumulator, the charge of the latter will be proportional to the number of sparks between the balls. The measuring jar may also be used to measure the overflow of electricity from one armature of an accumulator when the other is connected with an electric machine. In this case the outer coating of the jar is connected with the earth, and C is connected with the armature of the accumulator. There is no occasion to discuss minutely here the corrections necessary in the latter method of using the apparatus; on these and kindred points consult the account given by Mascart, *Traité d'Electricité Statique*, tom. i. §§ 313–316, and Riess, *l. c.*

The torsion balance of Coulomb is another instrument suited for the direct measurement of electrical quantity. For its construction and use see the article ELECTRICITY, p. 17.

Discharging electroscope.

The discharging electroscope of Gaugain belongs to the present class of instruments. It consists (fig. 2) of an ordinary (old-fashioned) gold-leaf electroscope, with the addition of a small knob B, connected with the metal sole of the instrument, and standing a little to one side of one of the leaves. The charge on any conductor is measured by connecting it with the knob A through a sufficient length of wet cotton to retard the discharge properly. When a certain amount of electricity has reached the gold leaf, it is attracted to the knob B and is discharged; it then falls back, is recharged, then discharged by contact with B a second time, and so on. It is found that the same quantity of electricity is discharged at each contact if the process be properly regulated; so that the whole charge on the conductor is measured by the number of oscillations of the gold leaf required to discharge it completely.[1]

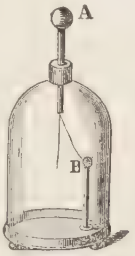

FIG. 2.—Discharging Electroscope.

The rest of the instruments (save one) to be described may be classified under the three heads given by Sir Wm. Thomson in his valuable report on electrometers,[2] viz., (1) repulsion electrometers, (2) attracted disc electrometers, and (3) symmetrical electrometers.

1. *Repulsion electrometers.*—The electroscopic needle of Gilbert is the oldest specimen of a repulsion electroscope. The linen threads of Franklin, and the double pendulum used by Canton, Dufay, and others, which was an improvement thereon, are typical of another species of electroscope coming under the same genus.

Cavallo's electroscope.

Cavallo's electroscope[3] (fig. 3) embodies the double pendulum principle. It consists of two fine silver wires loaded with small pieces of cork or pith, and suspended inside a small glass cylinder. Through the cap which closes the cylinder passes the stout wire from which the pendulums are suspended. This wire ends in a thimble-shaped dome A, which comes down very nearly to the cap; the outside of the cap and part of the wire are covered with sealing wax, and the object of the dome is to keep moisture from the stem, so that the electroscope could be used in the open air even in rainy weather. To add to the sensitiveness of the instrument two strips of tinfoil are pasted on the glass at B and C opposite the pith balls. An electroscope similar to this was used by Saussure.[4] Volta used a pair of straws instead of the pith-ball pendulums.

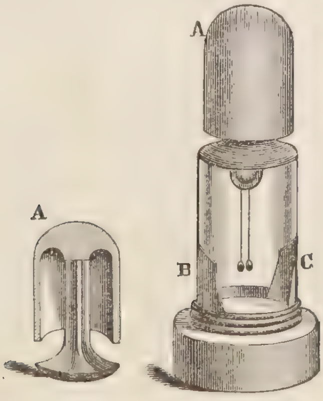

FIG. 3.—Cavallo's Electroscope.

Bennet's gold-leaf electroscope.

By far the most perfect form of electroscope on the double pendulum principle is the gold-leaf electroscope of Bennet.[5] Fig. 4 represents a modern form of this instrument. The gold leaves are gummed on the two sides of a flat piece of metal carried by a stout stem, which passes through the top of a glass shade and ends in a flat disc. By means of this disc we may convert the instrument into Volta's condensing electroscope (already described, see ELECTRICITY, p. 32). Inside the glass shade, and rising well over the leaves, stands a cylinder of wire gauze, which ought to be in metallic connection with the earth, or with some conductor whose potential is taken as the standard of reference. The introduction of the wire cylinder is due to Faraday, and is an essential improvement; it is absolutely necessary, in fact, to convert the instrument into a trustworthy indicator of differences of potential. It serves the double purpose of protecting the leaves from external disturbing influences, and of ensuring that the instrument always indicates the difference between the potential of the body connected with the leaves and another *definite* potential. Thus, if we insulate the sole of the electroscope, and connect A with the leaves, and B with the gauze, the divergence of the leaves corresponds to the difference between the potentials of A and B, and will always be the same for the same potential difference.[6] Hence, if the divergence of the leaves were read off by means of a properly constructed scale, the instrument might be used as a rough electrometer. The value of the graduation would of course have to be determined by experiment. Peclet did, as a matter of fact, use the gold-leaf electroscope in this way.

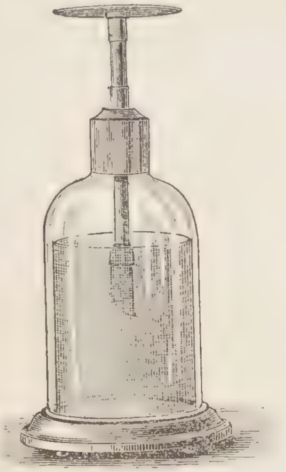

FIG. 4.—Bennet's Electroscope.

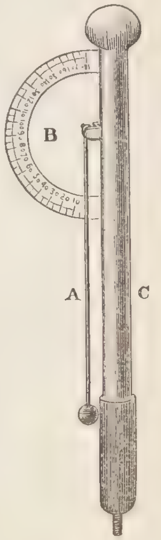

FIG. 5.—Henley's Electrometer.

Henley's electrometer.

The electrometer of Henley,[7] sometimes called Henley's quadrant electrometer (fig. 5), may be taken as the type of single pendulum electroscopes. It consists essentially of a pendulum A hinged to a vertical support C, which carries a vertical graduated semicircle B, by means of which the deviation of A from the vertical can be read off. This form of electroscope is, or was, much used for indicating the state of electrification of the prime conductors of electric machines. The stem is screwed into the conductor, and the divergence of the pendulum indicates roughly the charge.

Pendulum sine electrometer.

The sine electrometer of August, represented in fig. 6, is a modification of the single pendulum electroscope, analogous in principle to Pouillet's sine compass. A is a pendulum suspended by two threads to secure motion in one plane; B is a ball fixed to the case, and connected with a suitable electrode. Any charge is given to A; B is charged with q units of electricity; the case is turned through an angle ϕ in a vertical plane until the distance between A and B is the same as it was when both were neutral; then if the charge on A be always the same,

$$q \propto \sin\phi .$$

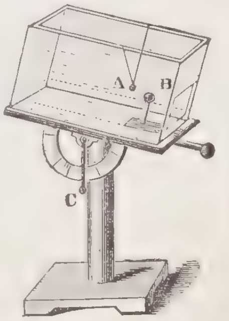

Fig. 6.—Sine Electrometer.

This instrument is interesting on account of the principle employed in its construction; but we are not aware that it has ever been used in practice.

Another class of instruments, in which the movable part is a horizontal arm turning about a vertical axis, may be looked upon as the descendants of Gilbert's electroscopic needle. The electrometer of Peltier and its modification into a sine electrometer (by Riess) are instruments of this class. Descriptions of both will be found in Mascart, §§ 291 and 292.

Dellmann.

Dellmann's electrometer (fig. 7) is constructed on a principle similar to that applied in the two instruments last named. D is a needle, formed of light silver wire, suspended by a fine glass fibre from a torsion head A. Below the needle is a piece of sheet metal NE, divided half through by a notch in the middle, and then bent in opposite directions on both sides of the notch, so that, when looked at end on, it appears like a Y. Underneath NE is a graduated disc PL, through the centre of which passes a glass tube F supporting NE, so that it can be raised or depressed by a lever G. Inside F is a spring by means of which the lever H, which serves as electrode, can be connected or disconnected at will with the metal piece NE. The whole contained in a metal case B, the lid of which is of glass, so that the position of the needle D on the graduation PL can be read off by means of the lens M. To use the instrument, the case is connected with the earth, the needle is brought nearly at right angles to NE, and NE is raised by means of G till the needle is in contact with it; then the electrode K is brought into communication with NE, and the body whose charge or potential is to be measured is connected with K. The connection with K is then suppressed, and NE lowered; and the needle, now free, is repelled by NE. If, by means of the torsion head, we bring the needle along to a fixed position relative to NE, the electrical couple will be proportional to the square of the charge communicated to NE and D, *i.e.*, to the square of the potential of the body connected with K, provided the capacity of the electrometer be negligible compared with that of the body. Hence the potential is measured by the square root of the torsion on the fibre when the needle is in a given position.

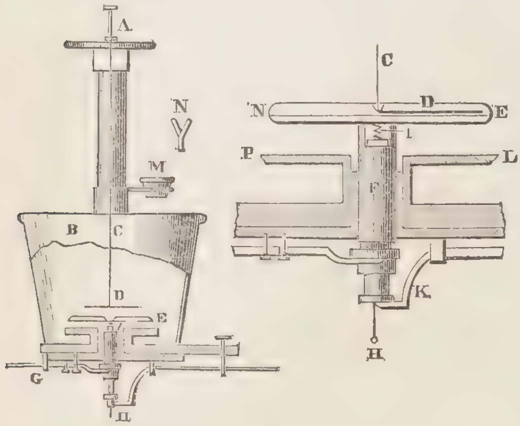

Fig. 7.—Dellmann's Electrometer.

The form of Dellmann's electrometer we have just described was that used by Kohlrausch.[1] It has been simplified by its inventor, and applied in his important investigations on atmospheric electricity.

Coulomb's balance might be used as an electrometer on the repulsion principle. Special care would, however, be necessary to avoid or to allow for disturbances arising from the case of the instrument, which ought under any circumstances to be coated wholly or partially with tinfoil on the inside, according to Faraday's plan. Sir Wm. Thomson did, in fact, design an electrometer of this description, and has given tables (*Reprint of Papers*, § 142) for reducing its indications. This type of electrometer has not come into general use.

Snow Harris.

II. *Attracted Disc Electrometers.*—The first idea of this kind of instrument is due to Sir William Snow Harris. One of the instruments in which he carried out the principle and the mode of using it will be understood from fig. 8. C is an insulated disc, over which is suspended another disc, hung from the arm of a balance, and connected with the earth. A weight w is put in a scale attached to the other arm of the balance. The insulated disc is connected with the internal armature B of a Leyden jar, whose outer armature is in connection with the suspended disc. Electricity is conveyed to B, and the quantity q measured by a small Lane's jar A, until the electric attraction at C is just sufficient to turn the balance. Snow Harris found that $w \propto q^2$. This and other laws established by him agree with the mathematical theory as developed in the article Electricity.[2]

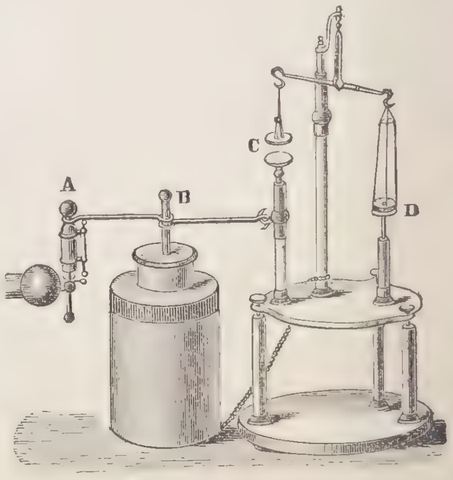

Fig. 8.—Snow Harris's Disc Electrometer.

Great improvements have been effected in this kind of electrometer by Sir William Thomson—(1) by his invention of the "guard ring" or "guard plate;" (2) by using the torsion of a platinum wire for the standard force; (3) by devising proper means for attaining a definite standard potential, and by protecting the vital parts of the electrometer from extraneous disturbance; and (4) by introducing sound kinematical principles into the construction of the movable parts.

Thomson's portable electrometer.

In order to illustrate these points it will be well to describe the portable electrometer (fig. 9), one of his simpler instruments, in detail.

The principal electrical parts of this electrometer are sketched in fig. 10. HH is a plane disc of metal (called the "guard plate") kept at a constant potential by being fixed to the inner coating of a small Leyden jar MM (fig. 9),

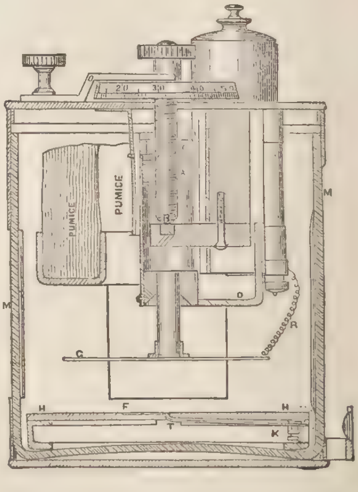

Fig. 9.—Section of Thomson's Portable Electrometer.

---

[1] *Pogg. Ann.*, 1842 and 1852.

[2] See also *Reprint* of Sir Wm. Thomson's Papers, § 158.

which forms the case of the instrument. At F a square hole is cut out of HH, and into this fits, as nearly as it can without danger of touching, a square piece of aluminium foil as light as is consistent with proper stiffness. One side of this disc is bent down, and then runs out horizontally into a narrow stem ending in a stirrup L—the whole being not unlike a spade. The sole of the stirrup consists of a fine hair, which moves up and down before a vertical enamelled piece bestridden by the fork of the stirrup. On the enamel are two small dots very near each other. When the hair seen through a small convex lens appears straight, and bisects the distance between the dots, the stirrup is said to be in the sighted position. The aluminium spade is suspended on a horizontal platinum wire stretched by platinum springs at its two ends, and is carefully balanced with its centre of gravity in the line of suspension, so that the only force other than electric that can affect it is the torsion of the wire, which acts like the string in the toy called the "jumping frog," or like the hair rope in the catapulta of the ancients. The spade is so arranged that F is as nearly as possible in the same plane with the guard plate when the hair is in the sighted position. It is the torsional couple exerted by the wire in this position that forms the standard force. The remaining important electrical part is the plane horizontal disc G.

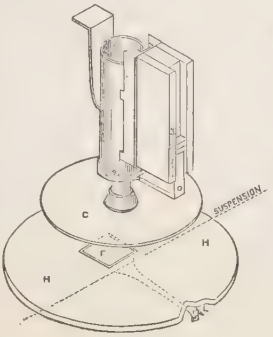

Fig. 10.

It is essential to the action of the instrument that we should be able to move the disc G parallel to itself and to HH through measured distances. The mechanism by which this is accomplished is a remarkable instance of the application of geometrical principles to mechanism, and the reader will do well to read Thomson's "Lesson to the instrument-makers" on this subject in the *Reprint* of his papers, § 369. The glass stem which carries G is fixed into the lower end of a hollow brass cylinder; in the upper end of the cylinder is fixed a nut AC, through which works a carefully cut screw ending in a rounded point B of polished steel. The point B rests on a horizontal agate plate let into a foot which projects from a strong vertical support fastened to the brass lid of the jar MM (fig. 9), and passes through a slit in the hollow cylinder. This vertical piece is fitted on one side with two **V** notches, into which the hollow cylinder is pressed by a spring fastened to the lid and bearing half-way between the **V**s, and on the other side with a rectangular groove in which slides the vertical part of a knee-piece D, in rigid connection with the hollow cylinder. D prevents the cylinder from turning round, but allows it to move vertically; it also carries a fiducial mark running opposite a graduation on one edge of the groove, by means of which whole turns of the screw are read off, fractions being estimated by means of a drum head. The nut AC is arranged in two parts, with a spring between them, to prevent "lost time" and secure steadiness (for details see paper cited above).

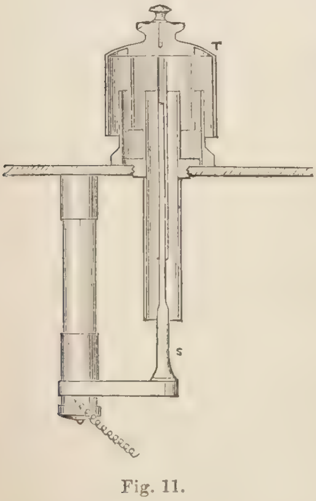

Fig. 11.

The disc G is connected by a spiral of fine platinum wire with the main electrode S, which is insulated from the lid of the box by a glass stem. The arrangement of this electrode is worthy of notice, and will be understood from fig. 11. The dome T is called the umbrella; its use is obvious. A similar, only less perfect device was noticed in Cavallo's electroscope. The vital parts of the instrument are all inside the coated jar, and therefore removed from disturbing influences; only it is necessary to remove some of the tinfoil opposite the hair in order to see it. The effect of this is counteracted by means of a screen of fine wire.

The use and the theory of the instrument are very simple. The body whose potential is to be measured is connected with the umbrella, which is raised in order to insulate the main electrode from the case, the last being supposed to be in connection with the earth. Let v be the potential of the inner coating of the jar, the disc, and guard plate, V that of the body and G, and d the distance between G and H when the hair is in the sighted position. Then, since F may be regarded as forming part of an infinite plate,[1] if its surface be S its potential energy will be $\frac{1}{2}S\sigma(v-V)$ (see Electricity, p. 32), *i. e.*,

$$\frac{S(v-V)^2}{8\pi d}.$$

Hence the attraction f on F will be given by

$$f=\frac{S(v-V)^2}{8\pi d^2}, \quad . \quad . \quad . \quad . \quad . \quad (1)^1$$

Here f is a constant, depending on the torsion of the suspending wire of the aluminium balance; hence, A^2 standing for $8\pi f \div S$, *i.e.*, A being a constant depending on the construction of the instrument, we have

$$v-V=Ad. \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

If we now depress the umbrella, so as to bring G to the potential of the earth, and work the screw till the hair is again in the sighted portion, we have, d' being the new reading of the screw,

$$v=Ad'. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Hence, from (2) and (3),

$$V=A(d'-d). \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

We thus get V in terms of A and the *difference* of two screw readings, so that uncertainties of zero reading are eliminated. The value of A must be got by comparison with a standard instrument, if absolute determinations be required.

Absolute electrometer.

Thomson's absolute electrometer (fig. 12) is an adaptation of the attracted disc principle for absolute determinations. We give merely an indication of its different parts, referring to Thomson's paper (*l. c.*) for details. B is an attracting disc, which can be moved parallel to itself by a screw of known step ($\frac{1}{50}$ in. or thereby).

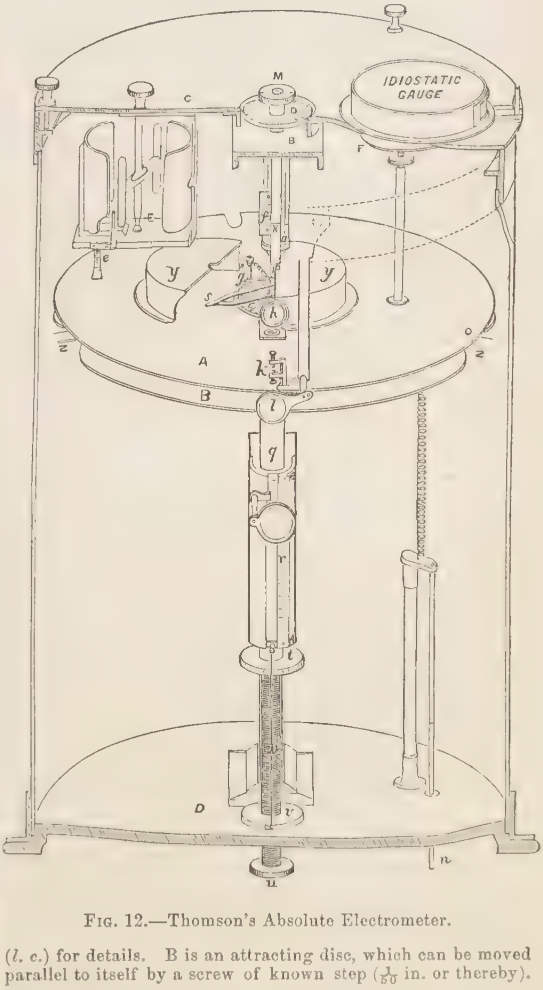

Fig. 12.—Thomson's Absolute Electrometer.

---

[1] Those who desire to know the degree of approximation here should consult Maxwell, *Electricity and Magnetism*, vol. i. § 217.

A is a guard plate, in the centre of which is a circular balance-disc of aluminium suspended on three springs, and connected by a spiral of light platinum wire with A. The disc can be raised or depressed into definite positions by means of a screw (the kinematical arrangements in connection with these screws are similar to that in the portable electrometer). A hair on the disc, an object lens *h*, a fiducial mark, and an eye lens *l* enable the observer to tell when this disc is in such a position that its lower surface is plane with the lower surface of A. *y y* are the halves of a box which screens the disc from electric disturbances. An idio-static gauge (consisting of an aluminium lever with guard plate, hair, and lens, as in the portable electrometer), placed over a plate F in connection with the guard plate, enables the observer to tell when the guard plate and the inside coating of the instrument (which forms a Leyden jar as in the portable instrument) are at a certain definite potential. And finally, a small instrument called the "replenisher" enables him to raise or lower the potential of A till this definite potential is reached.

Replenisher.

A short description of the replenisher will be in place here. It is represented pretty clearly at E (fig. 12). Two metal shields, in the form of cylindrical segments, are insulated from each other by a piece of ebonite; the left-hand one is in connection with the guard plate, the right-hand one with the case of the instrument (and therefore with the outer coating of the jar). A vertical shaft, which can be spun round by means of a milled head, carries two metal flies on the ends of a horizontal arm of vulcanite. Two small platinum springs (the front one is seen at *e*) are arranged so as to touch the flies simultaneously in a certain position just clear of the shields. Let us suppose the left shield along with A to be positively electrified, and the flies to be in contact with the springs; *e* being close to the left shield, the front fly will be electrified — and the back fly +. Suppose the shaft to revolve against the hands of a watch lying face up on the cover of the electrometer. The front fly carries off its — charge, and, when near the middle of the right shield, comes in contact with a spring connected with the shield. Being thus practically inside a hollow conductor, it gives up its — charge to the shield. At the same time the back fly gives up its + charge to the left shield. The result of one revolution therefore is to increase the + and — charges on the respective shields, or, in other words, to increase the difference of potential between them. By giving the machine a sufficient number of turns, the potential of A may be raised as much as we please; and, by spinning in the opposite direction, the potential can be lowered; so that, once A is charged, it is easy to adjust its potential till the hair of the gauge is in the sighted position.

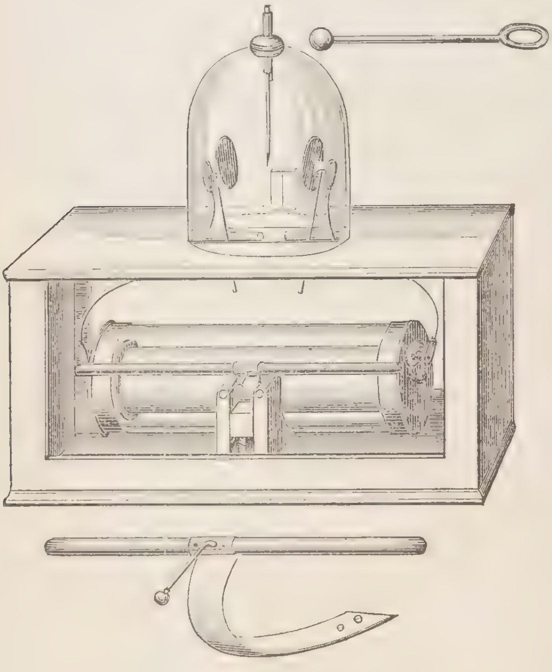

FIG. 13.—Dry Pile Electroscope.

To work the instrument, the electrode *n* of the lower plate B is connected with the guard plate to avoid all electrical forces on the balance; the hair of the balance is brought to the sighted position, and the upper screw reading taken; then a weight of *w* grammes is distributed symmetrically on the disc, the balance brought up again by working the screw, and the reading again taken. We thus ascertain how far the weight of *w* grammes depresses the balance. The weight is now removed, and the balance left at a distance above A equal to that just found. A is now charged, and its potential adjusted till the hair of the gauge indicates that the standard potential *v* is reached. Let it now be required to measure the difference between the potentials V and V′ of two conductors. Connect first one and then the other with *n*, and work the lower screw till the hair of the balance is sighted in each case, and let the screw readings reduced to centimetres be *d* and *d′*. Then, since the force on the disc in each case is *gw*, where *g* is the acceleration produced by gravity in a falling body in centimetres per second, we have by (1)

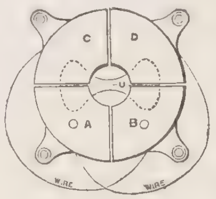

Fig. 14.

$$V - V' = (d' - d)\sqrt{\frac{8\pi g w}{S}}, \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where S denotes the area of the balance disc, or rather the mean of the areas of the disc and the hole in which it works. We thus get the value of V — V′ in absolute electro-static C. G. S. units.

Dry pile electroscope.

III. *Symmetrical Electrometers.*—Two instruments fall to be described under this head,—the dry pile electroscope, and Thomson's quadrant electrometer. The idea common to these instruments is to measure differences of potential by means of the motions of an electrified body in a symmetrical field of force. In the dry pile electroscope, a single gold leaf is hung up in the field of force, between the opposite poles of two dry piles, or, in later forms of the instrument, of the same dry pile. The original inventor of this apparatus was Behrens, but it often bears the name of Bohnenberger, who slightly modified its form. Fechner introduced the important improvement of using only one pile, which he removed from the immediate neighborhood of the suspended leaf. The poles of the pile are connected with two discs of metal, between which the leaf hangs. This arrangement makes it easier to secure perfect symmetry in the electric field, and allows us to vary the sensitiveness of the instrument by placing the metal plates at different distances from the leaf. In order to make the attainment of perfect symmetry still more easy and certain Riess[1] added a metal rod to the apparatus, which can be made to touch the two metal caps of the dry pile simultaneously, and then be removed, leaving the pile symmetrically electrified. This form of the electroscope, with the various improvements, is represented in Fig. 13.

Hankel[2] still further improved the dry pile electroscope by giving a micrometric movement to the plates, by substituting a galvanic battery with a large number of cells for the uncertain and varying dry pile, and by using a microscope with a divided scale to measure the motions of the gold leaf. With these improvements it became an *electrometer* of great delicacy and considerable range. Some of the experiments in which Hankel used it are alluded to in the article ELECTRICITY.

Quadrant electrometer.

In the quadrant electrometer of Sir Wm. Thomson, which is the most delicate electrometric instrument hitherto invented, the moving body is a horizontal flat needle of aluminium foil, surrounded by a fixed flat cylindrical box (fig. 14), which is divided into four insulated quadrants A, B, C, D. The opposite pairs A, D and B, C are connected by thin platinum wires. The two bodies whose potentials are to be compared are connected with the two pairs of quadrants. If A and B be their potentials, and C the potential of the needle, it may be shown (see Maxwell, *Electricity and Magnetism*, § 219) that the couple tending to turn the needle from A to B is

$$\alpha(A - B)\{C - \tfrac{1}{2}(A + B)\}, \quad . \quad . \quad . \quad . \quad (6)$$

where α is a constant depending on the dimensions of the instrument. If C be very great compared with $\frac{1}{2}(A + B)$, as it usually is, then the couple is

$$\alpha C(A - B) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

simply; in other words, the couple varies as the difference between the potentials of the quadrants. Some idea of the general distribution of the parts of the actual instrument may be gathered from fig. 15, which gives an elevation and a section of the instrument. The case forms a Leyden jar, as usual in Thomson's electrometers; the internal coating in this instance is formed by a quantity of concentrated sulphuric acid, which also keeps the inside of the instrument dry. The quadrants are suspended by glass pillars from the lid of the jar, and one of these pillars is supported on a sliding piece, arranged on strict kinematical principles, so as to be movable in a horizontal direction by means of a micrometer screw Y. This motion is used to adjust the position of the needle, when charged, so that its axis may fall exactly between the quadrants A, C, and B, D. A glass stem C, rising from the lid of the jar into a superstructure called the "lantern," supports a metal piece Z, to which is fastened a metal framework fitted with supports and adjustments for the bifilar suspension of the needle. A fine platinum wire drops from the needle into the sulphuric acid, thus connecting the needle with the inside coating of the jar. This tail wire is also furnished with a vane, which works in the acid and damps the oscillations of the needle. A stout aluminium wire rises from the needle, carries a light concave mirror T, and ends in a cross-piece to which are attached the suspension fibres. The aluminium stem and the platinum tail wire are defended from electrical disturbances by a guard tube, which is in metallic connection with the piece Z, and also, by means of a platinum wire, with the acid; it is through this, by means of the "temporary electrode" P, that the inside of the jar is charged. The two principal electrodes are P and M. Connected with Z is a metal disc S, attracting the aluminium balance of a gauge like that of the absolute electrometer. This gauge is well seen in the bird's-eye view given in fig. 16. A replenisher, like that in the absolute electrometer, is fitted to the lid of the jar, and by means of it the potential of the needle can be adjusted till the hair of the gauge is in the sighted position.

---

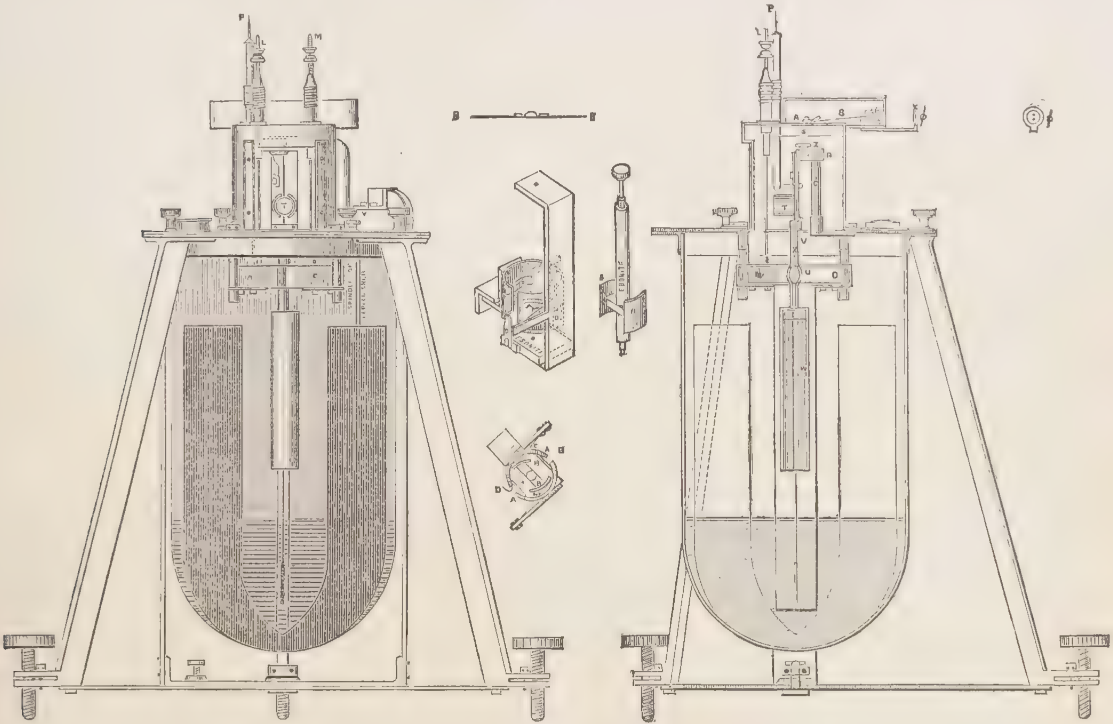

Fig. 15.—Elevation and Section of Thomson's Quadrant Electrometer.

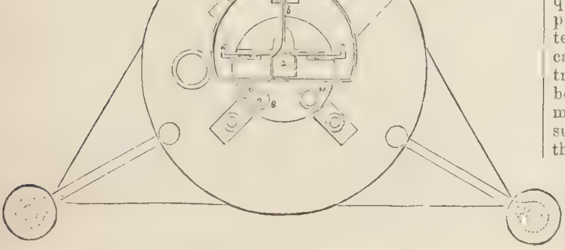

Fig. 16.—Thomson's Quadrant Electrometer.—Bird's-eye view.

The deflections of the instrument are read off by means of an image formed by the mirror T on a scale at the distance of a metre or so, the object being a wire which is stretched below the scale in a slit illuminated by a lamp. Within certain limits the deflections are proportional to the deflecting couple, *i. e.*, to the difference between the potentials of the quadrants A, D and B, C; but where this is not so, the instrument can easily be graduated experimentally.

For many purposes, especially in the lecture room, an instrument so complicated as the above is unnecessary and undesirable. A simpler form (fig. 17) of quadrant electrometer is now manufactured by Elliot Brothers, and answers most ordinary purposes very well.

Lappmann's capillary electrometer.

Capillary Electrometers.—Electrometers have recently been constructed by taking advantage of the fact that the surface tension of mercury is greatly affected by the hydrogen deposited on it when it is the negative electrode in contact with dilute sulphuric acid (see Electrolysis, p. 102). A quantity of mercury is placed in the bottom of a test tube, and communicates with a platinum electrode let in through the bottom of the tube; on the mercury is poured dilute sulphuric acid, and into this dips a tube drawn out into a capillary ending. This tube contains mercury down to a certain mark on the capillary part, the remainder being occupied with acid which is continuous with that in the test tube. So long as the mercury in the test tube is simply in metallic connection with that in the upper tube, the position of the mercury in the capillary part is stationary; but if an electro-motive force be introduced into the external circuit, acting towards the test tube, then hydrogen is deposited on the small mercury surface, its surface

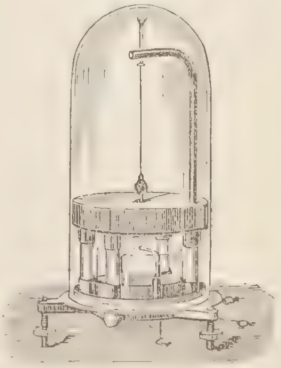

Fig. 17.—Quadrant Electrometer.

tension increases, and the pressure in the tube must be considerably increased to maintain the mercury at the mark. This increase of pressure is proportional to the electro-motive force within certain limits, hence we can use this arrangement as an electrometer.

Electrometric Measurement.—Several examples of electrometric measurement will be found in the article ELECTRICITY (pp. 17, 35, 36, 40, 44, etc.). We recommend in this connection the study of the sections on atmospheric electricity in Sir Wm. Thomson's *Reprint of Papers on Electricity and Magnetism*, and sections 220 and 229 in Clerk Maxwell's *Electricity and Magnetism*. We have been drawing throughout on Thomson's *Report on Electrometers and Electrometric Measurements*, but it will not be amiss to draw attention to it once more.

(G. CH.)

ELEMI. The resin thus termed in modern pharmacy is obtained by incising the trunk of a species of *Canarium* found in the Philippine Islands. It is a soft, more or less translucent, adhesive substance, of granular consistency and fennel-like smell, and colorless when pure, but sometimes gray or blackish from the presence of carbonaceous and other impurities. When exposed to the air it becomes yellowish in tint, and harder. It consists mainly of essential oil, and of an amorphous and a crystalline resin, the former easily soluble in cold, and the latter only in hot alcohol. Elemi is used chiefly in the manufacture of spirit and turpentine varnishes, which it enables to dry without cracking. As a constituent of a stimulating ointment, it has found a place in British pharmacopœias. In the Philippines it is employed for caulking ships, and is kneaded with rice-husks for torches (see Jagor, *Reisen in den Philippinen*, p. 79, Berlin, 1873). The word elemi, like the older term *animi*, appears to have been derived from *enhæmon* (Greek, *ἐναιμον*), the name of a styptic medicine said by Pliny to contain tears exuded by the olive tree of Arabia. This tree, according to Flückiger and Hanbury, is probably to be identified with the *Boswellia Frereana* of Birdwood, which flourishes in the neighborhood of Bunder Marayah, west of Cape Gardafui (see S. B. Miles, *Journ. R. Geog. Soc.*, xlii. p. 64). Mexican or Vera Cruz elemi, formerly imported into England, is afforded by the species *Amyris elemifera*, Royle; Mauritius elemi by another tree, *Colophonia Mauritiana*, D.C.; and Brazilian elemi by several species of *Icica*. For a paper "On the Chemistry of Elemi," see Flückiger, *Year-Book of Pharmacy*, 1874, p. 496.

ELEPHANT (*Elephantidæ*), a family of pachydermatous mammals belonging to the order Proboscidea, containing only a single existing genus and two species—the sole surviving representatives of the entire order. The elephants are characterized by great massiveness of body, constituting them the largest of living terrestrial mammals, by peculiarities in their dentition, and by the possession of a lengthened proboscis or trunk. The latter organ is a huge prolongation of the nose and upper lip, measuring usually from 6 to 8 feet in length, and almost wholly composed of a mass of muscles, numbering, according to Cuvier, nearly 40,000, and curiously interlaced, so as to produce the greatest diversity of motion. Its extremity contains the two openings of the nostrils by which the elephant breathes when swimming, as it sometimes does, with only the tip of its trunk above the surface, and through which it can fill the channels of its trunk with water, the flexibility of that organ enabling it to pour the liquid into its mouth or to squirt it over the surface of its body. By a peculiar valvular arrangement the water is prevented from penetrating into the bony nostrils. The extremity of the trunk is produced on the upper surface into a finger-like process, and ends beneath in a thick tubercle which acts the part of thumb to the prolongation above, while the whole is exquisitely endowed with the sense of touch, and so forms an organ of prehension comparable in many respects to the human hand. With it the elephant collects its food and drink, discovers the snares that are often set in its path, strikes its antagonist to the ground, and gives vent to its rage in a shrill trumpet-like sound, hence the French name of *trompe* for the proboscis, corrupted in our language into *trunk*. Without it the animal is helpless, being unable even to feed itself; and, as if conscious of the vital importance of this organ, the elephant is exceedingly cautious in using it, preferring when in combat with the tiger to fight with its trunk carried aloft, out of reach of its antagonist's claws. When the trunk is injured the elephant becomes furious with rage and pain, and can no longer be controlled by its rider.

The teeth of the elephant consist of two incisors, or tusks, as they are called, in the upper jaw, and six molars on each side of either jaw. The permanent tusks are preceded by small milk teeth, which, however, give place to their successors before the end of the second year. The tusks, proceeding from a permanent pulp, continue to grow during the elephant's life-time, and sometimes attain enormous size, examples having been known to weigh from 150 to upwards of 200 ℔ each. They consist almost entirely of ivory—a remarkably fine and elastic form of dentine—and are hollow for a considerable part of their length. They are also deeply imbedded in the skull; thus a tusk, about 8 feet long and 22 inches in girth, was found by Sir Samuel Baker to be imbedded to a depth of 31 inches. The tusks are invariably best developed in the male sex, and are regarded by Darwin as sexual weapons. Their almost vertical position, however, and the inability of the elephant to raise its head above the shoulder, render their use as offensive weapons somewhat difficult; nevertheless they are certainly employed as such in fighting with the tiger, the mode of using them depending, says Darwin, "on their direction and curvature"—thus the elephant has been known to toss a tiger to a distance of 30 feet with its tusks, when these were turned upward and outward, while it seeks to pin its foe to the ground when these organs have the usual downward direction. The tusks are largest in the African species, which feeds principally on the foliage and the succulent roots of trees, and in this species they are often used as levers in uprooting mimosa trees whose crown of foliage is beyond the reach of the upturned trunk. In Ceylon, on the other hand, where the elephant lives chiefly on grass and herbage, tusks are generally absent in both sexes. The bullets occasionally found imbedded in the solid ivory have evidently been shot into the upper part of the tusk, and, getting lodged in the pulp cavity, have been carried down by the growth of successive layers of ivory into the solid part of the tooth. The molar teeth consist of a series of transverse plates, composed of dentine, and coated with a layer of enamel, the whole bound together by the substance known as *crusta petrosa*, or cement. Each of these materials, possessing a different degree of hardness, wears away at a different rate from the others, and the uneven surface necessary for the proper trituration of the food is thus produced. Although the elephant may be said to have altogether six molars on each side of either jaw, at no time can more than one and a portion of a second be seen. These molars are not deciduous in the ordinary sense, but they grow from behind forward, and as the anterior part of the front molar gets worn away by degrees, its successor is gradually cutting its way through the gum, from which, however, it does not wholly emerge until the tooth in front has almost disappeared. This progression of the molar teeth continues throughout the greater part of the elephant's life, so that it may be said to be always teething. Six of such molars, each composed of a greater number of plates than its predecessor, are said to suffice it for life. The massiveness of the skull, and its height in front, to which the elephant owes something of its sagacious aspect, is due not to the great size of the brain—which is relatively small—but to the enormous development of the bones of the cranium, rendered necessary in order to give attachment to the powerful muscles of the head and trunk. The presence of large air cells, however, in the cranial bones, renders the skull light in proportion to its enormous bulk. The eyes in the elephant are small, and its range of vision, owing to the shortness and slight flexibility of its neck, is somewhat circumscribed; this, however, is of secondary importance to an animal living generally in dense forests, where the prospect is necessarily limited, and in the elephant is compensated for by exceeding keenness in the senses of hearing and smell. Its stomach resembles that of the camel in having a chamber which can be cut off from the proper digestive cavity for the storing of water; this is capable of holding 10 gallons. The contents of this chamber it is able to convey into its trunk, should it wish to indulge its body in the luxury of a shower bath. The elephant is an unwieldy creature, weighing fully 3 tons, and supported on colossal limbs, which from their straightness and apparent want of flexibility—an effect produced by the greater nearness of the knee and elbow to the ground than in most animals—were for centuries supposed either to be jointless, or to have such joints as could not be used. Such evidently was Shakespeare's belief when he wrote—

"The elephant hath joints, but not for courtesy;
His legs are for necessity, not flexure."

This delusion was further supported by the fact that the elephant often sleeps standing, its huge body leaning against a tree or rock. In lying down it does not place the hind legs beneath it, as is generally the case, but extends them backwards after the manner of a person kneeling. By this method the elephant can raise its huge weight with little perceptible effort. The feet are furnished with five toes, completely enveloped in a tegumentary cushion, and with four or five nails on each of the front feet, and three or four on the hind ones, according to the species. The skin of the elephant is thick and soft, and of a dark brown color. With the exception of a few hairs on certain parts of its body, it is naked, although individuals found in the elevated districts of Northern India are said to be more hairy than those inhabiting warmer regions, while the young everywhere, according to Tennent, are at first covered with a woolly fleece, especially about the head and shoulders, approximating in this respect to the mammoth which inhabited the Palæarctic region during Pleistocene times. From such facts Darwin regards it as probable that existing elephants have lost their hairy covering through exposure to tropical heat. The elephant continues to grow for upwards of 30 years, and to live for more than 100, there being well-authenticated cases of elephants that lived over 130 years in captivity. The female is capable of breeding after 15 years, and produces a single young one, rarely two, at a birth, the period of gestation extending over nearly 21 months. The young elephant sucks with its mouth, and not, as was formerly supposed, with its trunk.

Elephants are polygamous, associating together in considerable herds, under the guidance of a single leader, whom they implicitly follow, and whose safety, when menaced, they are eager to secure. These herds often do great damage to rice and other grain fields in cultivated districts, trampling under foot what they cannot eat. A slight fence is, however, generally sufficient to prevent their inroads, the elephant regarding all such structures with the greatest suspicion, connecting them probably, in some way, with snares and pitfalls. At times this usually inoffensive animal is subject to fits of temporary fury, and an elephant in "must," as this frenzied condition is termed, is regarded as the most dangerous of animals. When an elephant, from whatever cause, leaves the herd to which it belongs, it is not allowed to join the ranks of another, but ever after leads a solitary life. Those individuals are known as "rogues;" being soured in temper by exclusion from the society of their kind, they become exceedingly ferocious, attacking without provocation whatever crosses their path.

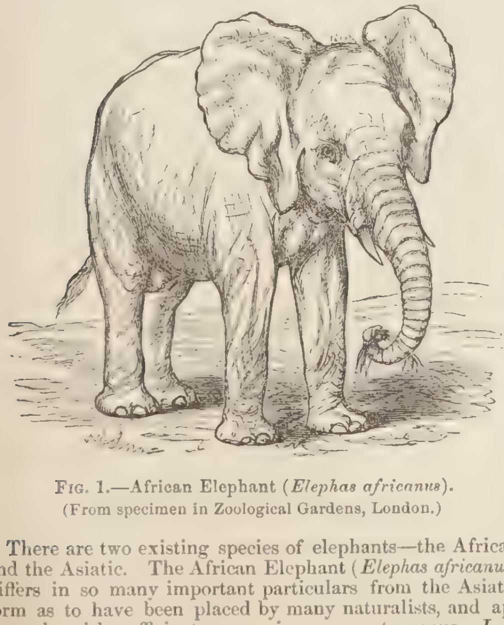

Fig. 1.—African Elephant (*Elephas africanus*).
(From specimen in Zoological Gardens, London.)

There are two existing species of elephants—the African and the Asiatic. The African Elephant (*Elephas africanus*) differs in so many important particulars from the Asiatic form as to have been placed by many naturalists, and apparently with sufficient reason, in a separate genus—*Loxodon*. The enamel on the crown of its molar teeth is arranged across the surface in lozenge-shaped figures, instead of the nearly parallel transverse ridges of the other species. Its ears are enormously large, completely covering the shoulder when thrown back; they have been known to measure 3½ feet in length and 2½ feet in width. Its forehead also is convex, and its back concave, while in the other the forehead is almost flat, and the back convex. The African elephant ranges over the whole of Africa south of the Sahara, with the exception of the Cape, where it formerly abounded, but from which it has been driven by man. In height it somewhat exceeds the Asiatic species, although never standing more than 11 feet high at the shoulders. Its tusks are also heavier, and occur in both sexes, although in the female they are comparatively small, a male tusk usually weighing about 50 ℔, while that of the female rarely exceeds 10 ℔. "The tusks of the African elephant," says Baker, "are seldom alike. As a man uses his right hand in preference to his left, so the elephant works with a particular tusk which is termed by the traders el-hadām (the servant); this is naturally more worn than the other, and is usually about 10 ℔ lighter." They roam among the long grass on the open plains, in the neighborhood of water, of which both species are excessively fond, feeding on the leaves and roots of trees, and using their tusks to overthrow such as are too strong to be pulled down by their powerful trunks. The traveller just quoted states that he has observed trees 4 feet 6 inches in circumference, and about 30 feet high, thus uprooted. He was assured by the natives, however, that in such cases the elephants assisted each other. Until comparatively recent times the natives of Africa hunted the elephant exclusively for its flesh, of which they are particularly fond; but since the arrival of the Arab traders, the natives, who formerly regarded the tusks as mere bones, and left them to rot along with the rest of the skeleton, have discovered the value of ivory, and this has led to the destruction of these animals on a much larger scale than formerly. England alone imports 1,200,000 ℔ of ivory annually, in order to obtain which, the lives of probably 30,000 elephants are sacrificed; and it has been estimated by a recent writer on this subject that, in order to supply the demand for ivory throughout the world, at least 100,000 individuals are annually slain. As the elephant is the slowest breeder of all known animals, should the slaughter continue on its present scale, the total extinction of tusk-bearing elephants is probably not far distant. The African elephant was in ancient times domesticated by the Carthaginians, who employed it in their wars with Rome. It was this species which crossed the Alps with Hannibal, and which the Romans, after the conquest of Carthage, made use of in war, in the amphitheatre, and in military pageants. No African race has since succeeded in reclaiming this highly intelligent and naturally docile animal—a fact often quoted in proof of the general inferiority of the negro race. Although common in Europe during the ascendency of the Roman empire, for centuries after it was almost unknown; and it was only in 1865 that the Zoological Society of London obtained a pair for their gardens. These are still living.

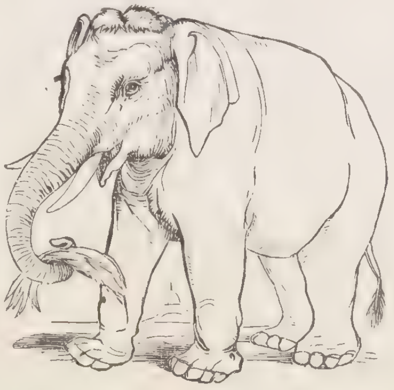

Fig. 2.—Asiatic Elephant (*Elephas indicus*).

The Asiatic Elephant (*Elephas indicus*) inhabits the wooded parts of the Oriental region, from India and Ceylon eastward to the frontiers of China, and to Sumatra and Borneo. It chiefly abounds in the jungle, and probably on this account is less active and fierce than the African form. It is not, however, partial, as was at one time supposed, to low grounds and sultry heat, abounding, in India and Ceylon, principally among the hilly and even mountainous districts, where the cold is often considerable. It is exceedingly sure-footed, and shows remarkable sagacity in its choice of a route over mountain districts. It feeds largely on grass, and, according to Tennent, the stems of plantain, stalks of sugar-cane, and the feathery tops of bamboo are irrresistible luxuries, and fruits of every description are eaten voraciously. The tusks grow to a considerable size in the male, but are wanting in the female; while in the Ceylon elephant, which by Schlegel, Tennent, and others is considered as forming, with the Sumatran elephant, a distinct species (*Elephas sumatranus*), tusks are also absent in the female, and only exceptionally present in the male. The latter, however, generally has a pair of upper incisors, known as "tushes," about a foot long, and one or two inches in diameter. The domestication of the Asiatic elephant dates from time immemorial, the earliest records in which it is mentioned showing that it was then chiefly employed in war. Elephants thus figured in the armies of the kings of India when these monarchs sought to repel the invasions of Alexander the Great and of Tamerlane; but, however formidable looking, they could not withstand the impetuous dash of well-armed and well-disciplined troops. The sabres of the invaders, aimed at their trunks, rendered the elephants totally unmanageable, and, in the confusion that ensued, they generally did more harm to their own side than to the enemy. Great wooden towers, capable it is said of accommodating 32 soldiers, were usually fastened to the back of the war elephant, and under cover of these the archers aimed their shafts. Since the introduction of firearms, the elephant has become still less serviceable as an "arm of war," and is now only employed in dragging heavy artillery and in the transport of baggage.

Elephants have been known to breed in captivity, and were thus bred, according to Ælian, in ancient Rome, but such an event in India or Ceylon is of the rarest occurrence, although in Ava, probably owing to the fact that the females are allowed to roam in the woods in a semi-wild state, such births are common. Domesticated individuals, in India and Ceylon, have thus been all reclaimed from the wild state, and the gaps caused by death can only be filled by fresh captures. Single wild males are often caught through the agency of tame females acting as decoys. When it is sought to capture whole herds, the Hindus and Singalese construct, in the heart of the forest, a vast inclosure known as a *keddah* or *corral*, formed of the trunks and branches of trees, with an opening on one side, into which the herd is driven. This, however, can only be accomplished by thousands of beaters making an extensive circuit round the haunts of the elephants, and gradually narrowing the circle until a comparatively limited area is completely inclosed. Around this, in order to diminish the chances of escape, fires are kindled at frequent intervals, and at last the beaters, with a general rush, and carrying lighted torches, close in upon the elephants, and the affrighted creatures, seeing no way clear except in the direction of the inclosure, make for it with all speed, and enter the corral. Once they are inside, the entrance is barricaded, and the entrapped elephants rush wildly about in the vain hope of finding a means of escape. When completely exhausted, they seek the centre of the inclosure, and there await motionless the progress of events. Several tame elephants, each bearing a *mahout* or keeper, and with a *nooser* following behind on foot, then enter the corral, and, the tame elephants mingling freely with the wild captives, the latter are put off their guard, and an opportunity is given to the attendant on foot to pass the noose of a rope, the other end of which is attached to the neck of one of the tame elephants, over each of its legs in succession. It is then securely tied to the trunk of a tree. The process of training, in which kindness and severity both play a part, occupies a comparatively short period, being greatly hastened by the sagacious co-operation of tame individuals. "This assistance," says Tennent, "can generally be dispensed with after two months, and the captive may then be ridden by the driver alone, and after three or four months he may be intrusted with labor, so far as regards docility." Males are generally more difficult to tame than females, and "rogues" are the most difficult of all; the worst, however, may be reclaimed by patience and kindness. In captivity elephants are subject to a great variety of diseases, and their rate of mortality is exceedingly high, more than half of those employed in the Government service of Ceylon dying after a single year of servitude. Their great strength, sagacity, and docility render them valuable as beasts of burden, and they have been largely employed in the East in road-making and bridge-building, being used for dragging timber, moving stones, etc. A powerful elephant is able, it is said, to lift and carry on its tusks a log of wood weighing half a ton. Having regard to the great expense of their maintenance, a working elephant consuming daily about 2 cwts. of green stuff and half a bushel of grain, as well as to their frequent illnesses, their employment is now considered less economical than that of horses, and consequently their use as beasts of burden is gradually decreasing. In India, however, the elephant is largely employed in hunting the tiger, the sportsman stalking this feline game from the comparative security of the *howdah* fixed on its back, while its motions are directed by the *mahout* seated on its neck.

White elephants are merely albinos. They are extremely rare, and great store is set upon them among the independent kingdoms of Further India—the chief white elephant at the court of Siam ranking next to the queen, and taking precedence of the heir apparent! Although not an object of worship in those countries, the white elephant is considered a necessary adjunct to royalty, the want of it being regarded as ominous; and in the 16th century a protracted war was waged between Siam, Pegu, and Aracan, in the course of which five kings were killed, for the possession of a particular white elephant.

Although now containing only two living forms, the family of elephants was in past geological periods much richer in species,—fossil remains of no fewer than 14 species of the genus *Elephas*, and a still larger number belonging to the allied genus *Mastodon*, having been found in the Tertiary formations, to which their remains are confined. The earliest elephants occur in the Miocene deposits of Northern India. In the Pliocene period they make their appearance in Europe, the most noteworthy species of that time being the *Elephas antiquus*, a southern form, which, surviving the rigors of the Glacial period, continued on into Pleistocene times. During the latter period elephants first appear in America, such forms as the Mammoth (*Elephas primigenius*) ranging over the northern regions of both hemispheres. The mammoth is undoubtedly the most interesting of all the extinct elephants, owing partly to its having co-existed with man, as is proved by the numerous flint implements and other human utensils found along with its remains, and also to the perfect state of preservation in which these have been found. At the beginning of the present century, a Siberian hunter discovered an entire mammoth, frozen in a block of ice, and another has since been found,—both so perfectly preserved that microscopic sections of some of the tissues were able to be made. These specimens showed that this huge creature, unlike existing elephants, was thickly clad in a covering of long dark hair, mixed at the roots with shorter hair of a woolly texture, that it possessed a mane, and that it had tusks of enormous length curved upwards to fully ¾ths of a circle. Its remains are found abundantly in England, and throughout the greater part of Northern Europe and Asia. They are specially abundant in Siberia, where the tusks are so plentiful and so well preserved as to form an important article of trade, supplying, it is said, almost the whole of the ivory used in Russia. In Malta the remains of two pigmy elephants—the one 4½ feet high at the shoulder and the other only 3 feet—have been discovered. The mastodons differed from the true elephants chiefly in their dentition, having a greater number of molars, and having these crowned with prominent tubercles arranged in pairs; they had also tusks in both jaws, those in the lower, however, never attaining great length, and often falling out during the lifetime of the mastodon.

ELEPHANTA ISLE, called by the natives Gharipur, a small island between Bombay and the mainland, is situated about seven miles from Bombay, 18° 57′ N. lat. and 73° E. long. It is nearly five miles in circumference, and the few inhabitants it contains are employed in the cultivation of rice, and in rearing sheep and poultry for the Bombay market. The island was, till within recent times, almost entirely overgrown with wood; it contains several springs of good water. But it owes its chief celebrity to the mythological excavations and sculptures of Hindu superstition which it contains. Opposite to the landing-place is a colossal statue of an elephant, cracked and mutilated, from which the island received from the Portuguese the name it still bears. At a short distance from this is a cave, the entrance to which is nearly 60 feet wide and 18 high, supported by pillars cut out of the rock; the sides are sculptured into numerous compartments, containing representations of the Hindu deities, but many of the figures have been defaced by the zeal of the Mohametans and Portuguese. In the centre of the excavations is a remarkable bust, thought to represent the Hindu Triad, namely, Brahma the Creator, Vishnu the Preserver, and Siva or Mahadeva the destroyer, but now supposed by some to be a triform representation of Siva alone. The heads are 6 feet in length, and are well cut, and the faces, with the exception of the under lip, are handsome. The head-dresses are curiously ornamented; and one of the figures holds in its hand a cobra di capella snake, whilst on the cap are, amongst other symbols, a human skull and a young infant. On each side of the Trimurti is a pilaster, the front of which is filled up by a human figure leaning on a dwarf, both much defaced. There is a large compartment to the right, hollowed a little, and covered with a great variety of figures, the largest of which is 16 feet high, representing the double figure of Siva and Parvati, named Viraj, half male and half female. On the right is Brahma, four-faced, on a lotus,—one of the very few representations of this god which now exist in India; and on the left is Vishnu. On the other side of the Trimurti is another compartment with various figures of Siva and Parvati, the most remarkable of which is Siva in his vindictive character, eight-handed, with a collet of skulls round his neck. On the right of the entrance to the cave is a square apartment, supported by eight colossal figures, containing a gigantic symbol of Mahadeva or Siva cut out of the rock. In a ravine connected with the great cave are two other caves, also containing sculptures, which, however, have been much defaced owing to the action of damp and the falling of the rocks. This interesting retreat of Hindu religious art is said to have been dedicated to Siva, but it contains numerous representations of other Hindu deities. It has, however, for long been a place, not so much of worship, as of archæological and artistic interest alike to the European and Hindu traveller. It forms a wonderful monument of antiquity, and must have been a work of incredible labor. Archæological authorities are of opinion that the cave must have been excavated about the tenth century of our era. The island is much frequented by the British residents of Bombay; and during his tour in India in 1875, the Prince of Wales was entertained there at a banquet. (See Rousselet's *L'Inde*, and Fergusson's *History of Architecture.*)

ELEPHANTIASIS (synonyms, *Elephantiasis Arabum, Barbados Leg, Boucnemia*), a term applied to a disease which is characterized by a peculiar overgrowth of the skin and subjacent textures. This condition appears to arise from repeated attacks of inflammation of the skin and concurrent obstruction of the veins and lymphatic vessels of the part. It may attack any portion of the body, but most commonly occurs in one of the legs, which becomes so enlarged and disfigured by the great thickening of its textures as to resemble the form of the limb of an elephant, whence the name of the disease is derived. The thickening is due to excessive increase in the connective tissue, which results from the inflammatory process, and which by pressure on the muscles of the limb causes them to undergo atrophy or degeneration. Hence the limb becomes useless. This disease is most frequently seen in tropical climates. When affecting the scrotum it frequently produces a tumor of enormous dimensions. There is in general little pain attending elephantiasis, which is essentially a chronic disease. The health, however, ultimately suffers, and serious constitutional disturbance is apt to arise. In the earlier stages of this disease great relief or even a cure may be effected by the persistent employment of wet bandages applied tightly to the limb from the toes upward, as recommended by Hebra. Ligature of the main artery of the affected limb has also been employed successfully, while amputation, which was formerly the only remedy employed, may occasionally be called for. In the case of tumors such as those already referred to the only remedy is excision. This disease is totally different from the so-called *Elephantiasis Græcorum*, or true leprosy, which will be afterwards described.

ELEUSINIA, a festival with mysteries in honor of the goddess Demeter and her daughter Persephone, so named, it was supposed, from the celebration of the most ancient of these festivals at Eleusis. The institutional legend connects the festival at Eleusis directly with the mythical incidents arising out of the rape of Persephone, known pre-eminently as Kore or the Maiden. Mourning bitterly for the loss of her child, who has been borne away by Hades or Aidoneus to the regions beneath the earth, the goddess Demeter wanders over sea and land in a vain search, until she comes to Eleusis. Here seated on a stone, and absorbed in her grief, she is accosted by the daughters of the Eleusinian king Celeus, and by them brought into his house, where she finds a home and becomes the nurse of his only son Demophoon. To make the child immortal she plunges him each night into a bath of fire; but before the work is done, the process is seen by his mother Metanira. Her terror excites the wrath of the mysterious stranger, who, throwing off her garment of humiliation, exhibits herself in all her majesty, and, rebuking the folly which has marred the fortunes of Demophoon, promises to prescribe the rites to be celebrated in the temple which is to be built to her honor on the hill above the fountain. In this temple she takes up her abode; but the grief from which she had been roused for a while by the jests and sarcasms of the serving maid Iambe again settles down upon her; and the earth, sympathizing with the Mourning Mother, refuses to yield her fruits until Zeus sends Hermes, his messenger, to the unseen land, and the maiden is restored to her mother at Eleusis, a name which means simply the trysting-place. The myth was thus localized in the little town, which retained its religious pre-eminence after it had been included in the Athenian state. Here was to be seen the stone on which the goddess was seated when the daughters of Celeus addressed her; here was the hill on which she bade them raise her shrine, and the well Callichorus, with its overshadowing olive tree, near which she had rested. Here also were the homes of Eumolpus, Triptolemus, and Diocles, whose descendants retained for ages their hereditary functions in the mysteries which attended the great annual festival. In the same way each incident in the legend was reproduced in the feast or in its accessories. Rude and coarse raillery addressed to the passers-by represented the rough jests of the maid Iambe; the posset of barley-meal mingled with water and mint, which the goddess drank in the house of Celeus, was still given to her worshippers; while the torch by which Hecate had guided her during part of her wanderings had its place in the ritual of the feast, every portion of which had thus her august sanction.

In later times, when Eleusis had lost its political independence, a temple of the goddess at Athens, called the Eleusinion, became to some extent the rival of the shrine at Eleusis; but the dignity of the ancient sanctuary was still marked by the solemn procession yearly made to it from Athens, during the greater of the two Eleusinian festivals. To this feast it would seem that at first Athenians only were admitted, the origin of the lesser festival being ascribed to a request made by Hercules to be initiated before his descent into Hades. Strangers being, it was said, excluded from the mysteries, the lesser Eleusinia was instituted to extend the benefit to all Greeks who might wish to share it. The great feast, celebrated yearly during the month of Boedromion (Sept.–Oct.) lasted nine days. The first day bore the name *ἀγυρμός*, the day of gathering at Athens for those who had been initiated in the lesser mysteries. On the second day, which was named from the cry Ἅλαδε μύσται, the mystæ went in procession to the sea-shore, and were there purified. The third was, it seems from the scanty notices which we have of it, a day of fasting. On the fourth a basket containing pomegranates and poppy seeds (the latter representing the stupefying power, Νάρκισσος, under whose influence the maiden Persephone was stolen away, the former denoting the fecundating principle by which the earth is prepared for the outburst of vegetation after the sleep of winter), was carried on a wagon in a basket whence the procession received the name Καλάθου κάθοδος. The wagon was followed by women carrying small cases, Κίσται μυστικαί, in their hands. On the fifth day, the day of lamps, the torches borne in procession to the temple at Eleusis denoted the wanderings of the goddess in search of her child, through the season of darkness and gloom. The sixth, the most solemn day of all, was known by the name of Iacchus, Ἴαχος, who in the Eleusinian legend is described as a son of Demeter, but who, according to the Theban tale, is, under his name Dionysus, the child of Zeus and Semele. The statue of this god, bearing a torch, was carried in solemn procession to Eleusis from the Athenian suburb of Kerameikos (Ceramicus). During the night which followed this celebration those who sought initiation were admitted to the last rites, in the presence of those only who, having been already initiated, were called ἐπόπται. After taking the usual oath of secrecy, they passed from the darkness of night into the lighted interior of the shrine, and there saw the things which none but Epoptæ could look upon, and which they were bound not to reveal. The imagination of later writers, not speaking from personal knowledge, ran riot in description of terrible ordeals and scaring sights undergone by the mystæ before the final splendors burst upon their eyes; while the fancy of Christians invested the preparatory rites with even greater horrors. Probably both the awfulness of the ordeal and the glories of the subsequent revelation were absurdly exaggerated. The whole of this part of the ritual is on its face symbolical of the passage through death to life, first in the case of the fruit-bearing earth, and then of the soul of man.

The real work of the festival was now over. The pilgrimage of the Mourning Mother had been traced from the moment when her child had been torn from her to the hour when by the Eleusinian fountain she was restored to her in all her loveliness. The seventh day was a day of jesting and raillery, denoting most probably the joy involved in the outburst of spring, although the institutional legend ascribed it to the efforts of Iambe or Baubo to dispel the grief of the goddess before the return of the maiden. The eighth day, called Epidauria, is said to have been added because on that day the god Asclepius (Æsculapius), arriving too late for the ceremonial of the sixth day, asked for initiation. This legend is a set-off to the one which was supposed to account for the institution of the lesser Eleusinia for the benefit of Hercules. The pouring of water or wine from two vessels, one held towards the east, the other towards the west, some mystic words being at the same time recited, gave to the ninth and last day its name Πλημοχόαι.

The nature of the mysterious doctrines set forth before those who were initiated in the Eleusinian festival is a question which belongs rather to the subject of mysteries in general. Enough has been already said to show that one great feature in this feast was the dramatic symbolism which described the revivification of the earth after the death of winter. This symbolism assumed forms which would explain their meaning even to the uninitiated. But the revival of nature would be inseparably associated with the thought of the life into which the human soul passes through the gateway of death; and in a festival where everything was dramatic the one truth or fact would be expressed by signs not less than the other. The Eleusinian legend represents Dionysus or Iacchus as the son of Demeter; and in the great Dionysiac festival at Athens the phallus was solemnly carried in procession, as in like state the veiled ship or boat of Athene was borne to the Acropolis. This ship or boat was represented by the mystic cists or chests carried by the pilgrims to Eleusis, and answers to the *yoni*, as the phallus corresponds to the *lingam* of the Hindu. The methods of initiation based on these signs might be gross or spiritual, coarse or refined, according to the genius of the people by whom they were used; nor would it be surprising if both these elements were more or less mingled in all mystical celebrations. There is no reason for supposing that the Eleusinian mysteries involved any more than this symbolical teaching which centres on the two ideas of death and reproduction; there is no valid ground for supposing that it involved less. Hence when Dr. Thirlwall expresses a doubt whether the Greek mysteries were ever used "for the exposition of theological doctrines differing from the popular creed," or when Mr. Grote asserts it to be altogether improbable that "any recondite doctrine, religious or philosophical, was attached to the mysteries or contained in the holy stories" of any priesthood of the ancient world, the remark is probably right, if by this recondite teaching be meant doctrines relating to the nature of God and the divine government of the world; but we should be scarcely justified in pushing it further.

How far in the Eleusinian mysteries the ritual was strictly Greek or even strictly Aryan is a question of greater difficulty, and perhaps of greater interest. It may be enough here to say that the Iacchus or Dionysus who in the Eleusianian legend is the son of Demeter is preeminently a Theban god, and that to Thebes especially is traced the introduction from Asia of that orgiastic worship in which the frenzy of the worshippers denoted the irresistible impulses by which the decay and reproduction of the natural world are governed.

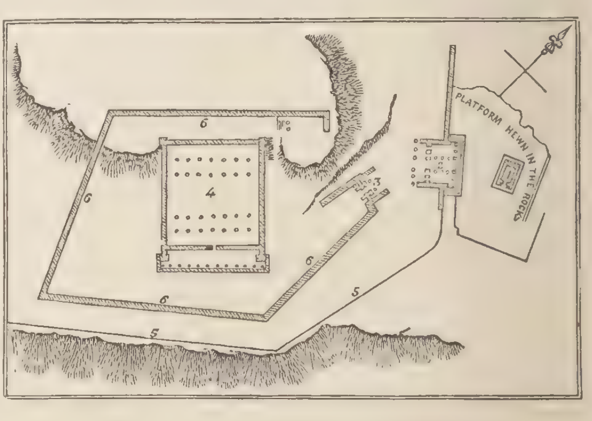
ELEUSIS, a small city of Attica about fourteen miles north-west of Athens, occupying the eastern part of a rocky ridge close to the shore opposite the island of Salamis. Like most of the other cities of Greece, its origin is ascribed to various fabulous characters, and, among these, to Ogyges, a fact which at least proves it to be of the highest antiquity. In the earlier period of its history it seems to have been an independent rival of Athens, and it was afterwards reckoned one of the twelve Old Attic cities. A considerable portion of its small territory was occupied by the plains of Thria, noticeable for their fertility, though the hopes of the husbandmen were not



Plan of the Sacred Buildings of Eleusis.

(From the *Inedited Antiquities of Attica.*)

1. Temple of Artemis Propylæa.
2. Outer Propylæon.
3. Inner Propylæon.
4. Temple of Demeter.
5. Outer inclosure of the sacred buildings.
6. Inner inclosure.

unfrequently disappointed by the blight of the south wind. To the west was the Campus Rharius, Πεδίον Ῥάριον, or Rharian Plain, where Demeter is said to have sown the first seeds of corn; in the midst of the Campus was the Καλλίχορον φρέαρ, a well round which the Eleusinian matrons are said at first to have danced in honor of the goddess; and on its confines was the field called Orgas, planted with trees consecrated to Demeter and Proserpine. To the traveller approaching by the Sacred Way from the east the first building that presented itself was the temple of Triptolemus, the site of which is now occupied by the little church of St. Zacharias; and next came a temple dedicated to Artemis Propylæa and Poseidon, constructed entirely of Pentelic marble. Entrance into the outer *peribolos*, or inclosure of the great temple of the mysteries was obtained by means of a portico built in imitation of the propylæa of the Athenian citadel; into the inner *peribolos* by another dedicated by the consul Appius Claudius Pulcher, in 54 B.C., and executed by his nephew Claudius Pulcher and Marcius Rex. The temple itself, sacred to Demeter and Kora (Ceres and Proserpine), was considered one of the most beautiful productions of the genius of Greece. The original foundation is said to have been due to Pandion II., and Clemens Alexandrinus places it even 120 years earlier, in the reign of Lynceus. Its position and riches naturally exposed the temple to the attacks of the enemies of Attica; and though defended by a strong fortress, it was seldom able to make any lengthened resistance. Cleomenes, king of Sparta, dared to violate its sacred precincts; but if we may believe the Athenians, he was soon after seized with a retributive fit of madness. The Persians burnt it to the ground after the battle of Platæa; but scarcely had they retired from Greece, when the Athenians determined to rebuild it with more than its original magnificence. Ictinus, the architect of the Parthenon, was ordered to draw up the plan of the new edifice. He adopted the Doric order of architecture, without the erection of pillars in front of the building. We know not whether he lived long enough to carry his plan into execution; but it was during the splendid administration of Pericles, and under the cultivated taste of Phidias, that the temple was completed in all its magnificence. The mystic cell (μυστικὸς σηκός, ἀνάκτορον, or τελεστήριον) was begun by Corœbus, but he lived only to finish the lower row of columns, with their architraves. Metagenes, of the district of Xypete, added the rest of the entablature, and the upper row of columns. Xenocles of Cholarge built the dome on the top. A portico was long afterwards added by Demetrius Phalereus, who employed for that purpose the architect Philo. This magnificent structure continued to exist till the hordes of Alaric completed its overthrow in 396 A.D. The city disappeared on the destruction of the temple; and upon the site nothing is now found but a miserable village called *Lefsina* (Λευσῖνα), or Lepsina, amidst the ruins of the sacred edifice. The coins of Eleusis are still common, representing Demeter drawn by dragons or serpents, and bearing the inscription ΕΛΕΥΣΙ or ΕΛΕΥ within a wreath of ears of corn. A colossal statue of the goddess, regarded by the inhabitants as their patroness and protectress, was removed to England in 1801, and is now preserved in Cambridge.

ELEUTHEROPOLIS, an ancient city of Palestine, about 25 miles from Jerusalem, on the road to Gaza, identified by Robinson with the ruins at the modern village of Beit Jibrin. It is mentioned by Ptolemy under the older name of Baitogabra, and did not acquire the title of Eleutheropolis, or Free City, till the Syrian visit of the emperor Septimius Severus. In the time of Eusebius it was so well known that he uses it as a central point from which to measure the distances of more than 20 other towns. The year 796 saw its complete destruction; and it was still in ruins when the crusaders of the 12th century chose Bethgebrim, as they called it, as the site of one of their fortresses. After the battle of Hattin it was captured by the Saracens; and though King Richard of England again obtained possession, it finally fell into the hands of Bibars. The fortress and a fine old chapel still remain. According to a local tradition, it was at Eleutheropolis that the fountain rose from Samson's "jaw-bone of an ass." Epiphanius, a native of a neighboring village, is frequently called an Eleutheropolitan.

ELGIN, or MORAYSHIRE, a maritime county in the north of Scotland, bounded on the N. by the Moray Firth, along which it extends for thirty miles, on the E. and S.E. by Banffshire, on the S. and S.W. by Inverness-shire, and on the W. by Nairnshire. The distance from the sea to its furthest inland point is 33 miles. It contains, since the alterations made by the Inverness and Elgin County Boundaries Act, 1870, about 487 square miles, or 312,375 acres, nearly one-third of which may be considered as under cultivation. As thus limited, the county comprises but the eastern portion of the ancient province of Moray, which extended from the Spey on the east to the river Beauly on the west, and from the sea to the Grampians southwards.

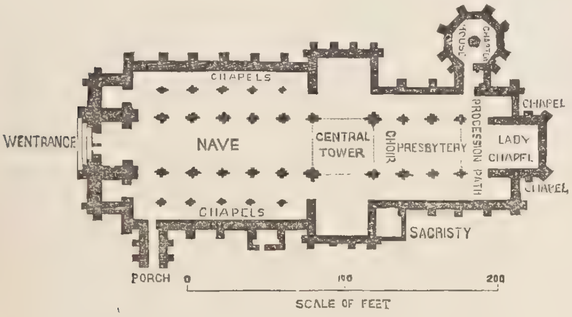
Elginshire naturally divides itself into two portions, distinguished not less by physical aspect and geological structure than by the products of the soil—the seaboard and the upland. The surface of the former, as its local name, "laigh o' Moray," implies, is level, rising, however, between the mouth of the Lossie and Burghead, and westward from Elgin, into ridges of some height. Throughout this district the prevailing rock is sandstone, overtopped to the south and east of Elgin, and in several other localities—as at Lossiemouth—by a species of limestone or "cherty rock." From the mouth of the Spey west and south till the gneissose rocks of the uplands are reached, the sandstone is of a dark red color, and belongs undoubtedly to the Old Red or Devonian formation. Elsewhere in the district it is gray or yellow, apparently overlying beds of this Old Red, but almost destitute of fossils, except in the coast ridge and the parallel portion of the inland ridge already mentioned, where are the famous reptiliferous strata whose age has lately given rise to so much discussion. Oolitic patches, indicative of a formation of mesozoic age having once existed in the neighborhood, are also found scattered between Elgin and the sea. Favored by an excellent climate and rich soil, the lowlands of Moray have been long noted for their fertility. Wheat, barley, and oats are all grown in great perfection, and exotic fruits of various kinds ripen freely in the open air. Since the beginning of the present century, agricultural pursuits have been carried on in a spirit that has greatly increased the natural resources of the district. Within the same period the breeding and rearing of cattle has become one of the most profitable occupations of the farmer; and some of the finest shorthorned and polled cattle in Scotland are to be seen here, as well as crosses between these two breeds. On a number of the more extensive farms large flocks of sheep, chiefly Leicesters, are kept all the year round. The upland portion of the county is hilly, gradually rising higher and higher above the level of the sea,—the loftiest of its ridges being the Cromdale hills, one point of which has an elevation of 2328 feet. Here the rocks are metamorphic, with associated limestones and veins of granite, closely resembling the rocks elsewhere met with around the Grampians, between the Old Red and the central masses of granite and other once molten matter. Their strike is N.E. and S.W., the same as prevails between Aberdeen and Argyll. The climate of this district is much colder and damper; oats is the principal cereal, barley being confined to the glens and straths; the cattle partake more of the character of the Highland breed; and the black-faced sheep takes the place of the Leicester.

The rivers of Elginshire are three in number—the Spey in the east, the Lossie in the centre, and the Findhorn in the west. The first of these rises in Badenoch, a district of Inverness-shire, and after flowing north-east for a distance of about 120 miles (including windings), of which 50 are in Elginshire, falls into the Moray Firth at the village of Garmouth. It is said to be the most rapid river in Scotland, and to discharge a larger volume of water than any other Scottish stream, the Tay alone excepted. The Spey receives a number of tributaries, the chief of which are the Truim, the Dulnain, the Avon, and the Fiddich. The Lossie, by far the smallest of the three, and the only one of them that rises within the boundaries of the county, issues from a small loch of the same name in the uplands, and, after a somewhat tortuous course of about 25 miles, empties itself into the sea at Lossiemouth. The Findhorn, like the Spey, has its source in Inverness-shire, in the western slope of the Monadleadh mountains, which for a number of miles form the water-shed between it and the Spey. It then flows through parts of Nairn and Moray shires, and after running in a north-easterly direction for about 70 miles, of which not more than 11 are within the boundaries of the latter, reaches the sea at the village of Findhorn, where it expands into an estuary of some extent. For seven or eight miles after it enters Morayshire, the scenery along its banks is among the grandest and finest of the kind in Britain. Of all the rivers affected by the memorable rain-fall that occurred in the north of Scotland in August, 1829, none rose higher or committed greater havoc than the Findhorn. Both the Spey and the Findhorn abound in salmon and grilse, the fisheries for which are very valuable. West of the estuary of the latter are the Culbin sand hills, some of which, though ever shifting, have an average height of 118 feet. They cover what was 200 years ago an extensive estate, then comprising thousands of acres of the finest land, but now presenting an impressive scene of desolation and solitude. The lochs are small and few in number. The sea-coast is very exposed; rocky between Lossiemouth and Burghead, elsewhere low and sandy. Of its few harbors, Burghead is the most sheltered by position; but a good deal has been done by art for that of Lossiemouth, in which a number of vessels may sometimes be seen lying. For a number of years the herring fishery was successfully prosecuted at Lossiemouth, Burghead, Hopeman, and Findhorn, there being at one season as many as 120 boats fishing from Lossiemouth alone; but latterly it has been more or less a failure, owing to the herring, for some cause or other, having become scarcer in their old feeding grounds. Large quantities of haddock, cod, and ling are caught in the firth and sent south during the winter and spring. Elginshire is not particularly rich in minerals. No true coal has yet been discovered within its limits; and though iron ore is said to exist in the higher parts, it cannot, owing to the absence of coal, be profitably worked. Lead occurs to the west of Lossiemouth. Attempts formerly made to extract it from the rock in sufficient quantities to prove remunerative failed; but operations lately undertaken give promise of success. The yellow sandstone of the lower district is a building stone of superior excellence, practically inexhaustible,—the distinct glacial striæ, seen on most of its outcropping strata, proving how capable it is of resisting all atmospheric influence. The rough, impracticable gneissose beds of the upper district offer no favorite building stone, and true slates are unknown. The plantations consist of larch, fir, and to a less extent oak. The country is well wooded, but since the introduction of railways a considerable quantity of timber has been cut down. The forest of Darnaway, on the left bank of the Findhorn, is believed to be a remnant of the natural wood with which a great part of Scotland was once covered. The manufactures are by no means important. Shipbuilding is carried on at the mouth of the Spey, though not on a large scale. The Highland Railway, which traverses Morayshire from east to west, is joined at Alves and Kinloss by branches from Burghead and Findhorn respectively, the latter of these being at present (1878) disused. At Forres the main line of the same railway strikes off for Perth by the valleys, first of the River Findhorn and afterwards of the Spey, the Garry, and the Tay. The great North of Scotland Railway has also been extended from Keith to Elgin by a somewhat circuitous route, and is connected with the Highland Railway at Boat of Garten in Strathspey. The Morayshire Railway, joining Elgin to Lossiemouth, the first line formed north of Aberdeen, is now worked as a branch of the Great North. In 1872 there were in Elginshire 251 owners of land of 1 acre and upwards in extent, the principal among them being the earl of Seafield (Castle Grant), 96,721; the earl of Fife (Innes House), 40,951; Sir William G. Gordon Cumming, Bart. (Altyre House), 36,387; the earl of Moray (Darnaway Castle), 21,669; and the duke of Richmond and Gordon (Gordon Castle), 12,271. In the same year the annual value of the land in the county was estimated to be upwards of £200,000. The number of inhabited houses was 8452. The aggregate population of the whole county was, in 1831, 34,498; in 1841, 35,012; in 1851, 38,959; in 1861, 44,218; in 1871, 43,612. It unites with Nairnshire in returning a member to parliament. In 1877–78 the combined constituency was 1837, of which 1555 voters were in Elginshire. The county contains 22 parishes. Ecclesiastically it is part of the synod of Moray, the limits of which are nearly co-extensive with those of the ancient province, except that Strathbogie has been added.

There are two royal burghs in Elginshire—Elgin, the county town (for which see below), and Forres. Forres (population in 1871, 3959) must have been a place of some importance at an early date, though it was subsequently overshadowed by the neighboring burgh or city. Its castle was for 300 years the official residence of the hereditary sheriffs of Moray; and of the lands anciently bestowed upon it by royal favor it still possesses upwards of 1000 acres. The town is pleasantly situated at the foot of the Cluny Hills, several wooded eminences traversed in all directions by public walks that are sheltered alike from the heat of summer and from the cold of winter. On the southern slope of one of them is a large hydropathic establishment. Forres being one of the centres of railway communication in the north, all parts of the country are easily accessible from it. Its most noteworthy memorial of antiquity is Sweno's Stone, one of those remarkable sculptured monuments peculiar to the north-east of Scotland. Besides the villages on the coast mentioned above, Elginshire contains those of Fochabers, Rothes, and Grantown.

In all parts of the county the oldest names of places are Celtic, showing clearly what race had at one time been in possession of the soil. At the dawn of authentic history we find Macbeth, Ri or Mormaer of Moray, in rebellion against "the gracious Duncan." The sequel is well known. A century or so later there was a great influx of strangers into Moray—Normans, Saxons, and Flemings—who got large grants of land from David I. and his immediate successors. It was in those days that the family of De Moravia became the owners of the fairest part of the province. At the same period, and under the fostering influence of the same kings, the church acquired extensive lands in Moray. In addition to the cathedral at Elgin, there were the abbey of Kinloss, and the priories of Urquhart and Pluscarden, all well endowed. Chief among its ruined castles are Spynie Palace, the country residence of the bishops of Moray; Duffus, once the home of the De Moravias, and "still the admiration of the antiquary;" Rothes, for centuries the seat of the Leslies; and, built on an island in the middle of a loch of the same name, Lochindorb, which was in the 13th century one of the mountain strongholds of the then powerful family of Comyn. Another interesting locality is the promontory of Burghead, or "the Broch," as it is still familiarly called, anciently the site of a Christian church, the date of the planting of which there is some evidence to show goes back as far as the days of Columba, and probably the site also of one of those brochs or fortresses so common in the more northern parts of the kingdom, the nationality of whose builders is still a matter of dispute. The headland was afterwards turned, apparently by the destruction of these or other buildings, into a kind of fortified camp, a plan of which has been preserved by General Roy, in his *Military Antiquities of North Britain.* Except a remarkable well cut in the solid rock, and of older date at least than the mounds sketched by Roy, few vestiges of the former importance of Burghead now remain.

Elgin, a royal and parliamentary burgh of Scotland, and the county town of the above county, which, from its having been once the see of a bishop, and occasionally the residence of the kings of Scotland, claims for itself the designation of a city. It occupies a sheltered situation on the banks of the small river Lossie, about five miles from where the latter enters the Moray Firth. From Edinburgh it is distant by railway 200 miles, from Aberdeen 71, and from Inverness 36¾. Elgin has one main street about a mile in length, with several others running parallel or at right angles to it. Northwards across the Lossie is the suburb of Bishopmill, in a different parish, but within the parliamentary boundaries of the burgh. In the outskirts of Elgin proper, as well as in the neighborhood of Bishopmill, are a large number of villas, most of them built within the last thirty years. On an eminence at the west end of the High Street stands Gray's Hospital, opened for the reception of patients in 1819. It was built and is maintained out of the proceeds of a legacy of £24,000, bequeathed for the purpose by Alexander Gray, surgeon, H.E.I.C.S., a native of the town. The site of the old church of St. Giles is occupied by the parish church, erected in 1828, at an expense of nearly £9000. At the eastern extremity of High Street is Anderson's Institution, "for the education of youth and the support of old age," opened in 1833. This building cost nearly £12,000. Its founder, the son of a poor woman who cradled him among the ruins of the cathedral, rose from the ranks to be a major-general in the service of the East India Company, and bequeathed for the erection and endowment of this institution £70,000. On the top of Ladyhill rises a column 80 feet high, surmounted by a statue of the last duke of Gordon in his robes as chanceller of Marischal College and University, Aberdeen. Along the High Street are many handsome modern structures, erected mainly for business purposes, prominent among which are those belonging to various banking companies. Other public buildings and institutions are—the District Asylum, the Assembly Rooms, the Market Buildings, the Burgh Court-house and the County Buildings, the Club-house and Reading-room, the Museum, and the Morayshire Union Poorhouse. The places of worship besides the parish church, are the High and South Free churches, the Moss Street and South Street U.P. churches, the Congregational church, and the Episcopal, the Roman Catholic, and the Baptist chapels, all of them of recent date. Elgin is well supplied with schools, the old grammar school of the burgh being represented by the Elgin Academy. The ruins of the cathedral are situated at the east end of the town. In 1390, after it had stood 166 years, the "Wolfe of Badenoch," a natural son of King Robert II., having quarrelled with Bishop Barr, set fire to the splendid pile. The destruction thus wrought was repaired but slowly, owing in part to the lawless condition of the country in those days. After the Reformation, the lead was stripped from the roof in 1568 by order of the Privy Council, and shipped for Holland to be there sold. The building being thus exposed gradually yielded to the influence of the weather, and in 1711 the great central tower fell to the ground. It remained in a neglected state till about 1820, when it was taken possession of in the name of the Crown by the Commissioners of Woods and Forests. The cathedral is now well inclosed, and every attention paid to its preservation from further decay. Adjoining are the ruins of the town house of the bishops of Moray, whose official residence was Spynie Palace, situated about three miles to the north. The Museum, already mentioned, contains, besides objects from various parts of the world, a very complete collection illustrating the natural history and antiquities of the county, chiefly formed through the zeal and activity of a band of local workers.



Ground-plan of Elgin Cathedral.

The trade of Elgin is largely connected with its weekly and other markets. It has, however, two woollen manufactories, a tanwork, one or two small iron foundries, two breweries, and some other industrial establishments. Its port is Lossiemouth, with which it is connected by railway, but it has likewise railway communication with Burghead. The railway from Aberdeen to Inverness passes the town, and a branch line strikes off southward here that traverses Strathspey. There are several newspapers, one of which is published twice a week; and, besides a circulating library and book clubs, Elgin has a literary and scientific society in connection with the Museum. Attracted by early associations, by the salubrity of its climate, or by other advantages it enjoys, not a few gentleman of independent means make it their home. The municipal corporation of the burgh and city of Elgin consists of a provost, 4 bailies, and 12 councillors; and, along with Banff, Cullen, Inverurie, Kintore, and Peterhead, it returns one member to the imperial parliament. Population in 1871, 7340; parliamentary constituency in 1877–8, 918.

The first notice we have of Elgin carries us back beyond the middle of the 12th century. In a charter granted by David I. to a priory in its neighborhood, it is referred to as "my burgh of Elgin." Certain privileges bestowed on its citizens by this king were afterwards confirmed and extended by his grandson, William the Lion, who seems to have oftener than once held his court in its castle. William's son and successor, Alexander II., frequently resided there, and it was in his reign that it became an episcopal city. When Edward I. of England entered Scotland in the year 1296 at the head of his army, he marched northwards as far as Elgin, where he remained some days. The town or city must then have been a place of considerable importance. Its castle, the ruins of which are still to be seen on a green mound near its western boundary, called Ladyhill, was one of the seats of Scottish royalty. Beneath this fortress, and commanded by it, ran the single street—now High Street—that formed the ancient town, with the East and West Ports at either end. Two short lanes branching off near its centre led to the North and South Ports respectively. At one time these four Ports were no doubt connected by some defensive works. About half-way between the East and West Ports stood a church dedicated to St. Giles, the patron saint of Elgin, and surrounded by a graveyard. A little to the west of this church was the Tolbooth. There is evidence that the clergy and landed proprietors of the town and neighborhood had even then residences within the limits of the town. But its glory was its noble cathedral, founded in 1224 by Bishop Andrew Moray, and declared by Billings to have been "the most stately and the most beautifully decorated of all the ecclesiastical edifices of the country." Clustered round the cathedral were the deanery, and the manses and gardens of the canons,—the whole constituting the "College," and inclosed by a stone wall 20 feet high and 6 feet thick. Among its other ecclesiastical buildings were two monasteries one of black and the other of gray friars, and a chapel to the Virgin connected with the castle. The Reformation, by stripping Elgin of its ecclesiastical honors, greatly reduced its influence. It continued, however, till towards the close of the last century to be the winter residence of the chief landowners of the district, some of whom lived in houses surrounded by large gardens, others in mansions fronting the street and resting on squat pillars and arches. A characteristic specimen of the latter is shown by Billings in his *Baronial and Ecclesiastical Antiquities of Scotland*. The merchant gentlemen of the town, some of whom carried on a very extensive import and export trade in all sorts of commodities, occupied dwellings of the same class, while the humbler burgesses lived in smaller houses, whose crow-stepped gables were turned to the main street. With the change that, owing to various influences, came over the social habits of the upper classes in the course of the last century, the importance of Elgin was a second time threatened; but when the agricultural resources of the country began to be more fully developed, its position as the centre of one of the most fertile districts of Scotland gave a new impetus to its prosperity.

(J. M'D.)

ELGIN, Thomas Bruce, Seventh Earl of (1766–1841), was born July 20, 1766, and succeeded his brother in the Scotch earldoms of Elgin and Kincardine when only seven years of age. He was educated at Harrow and Westminster, and, after studying for some time at the university of St. Andrews, he proceeded to the Continent, where he prosecuted the study of international law at Paris, and of military science in Germany. When his education was completed he entered the army, in which he rose to the rank of general. His chief attention was, however, devoted to diplomacy. In 1792 he was appointed envoy at Brussels, and in 1795 envoy extraordinary at Berlin; and from 1799 to 1802 he was envoy extraordinary at the Porte. It was during his stay at Constantinople that he formed the purpose of removing from Athens the celebrated sculptures now known as the Elgin Marbles. His doing so was censured by some as vandalism, and doubts were also expressed as to the artistic value of many of the marbles; but he completely vindicated himself in a pamphlet published in 1810, and entitled *Memorandum on the Subject of the Earl of Elgin's Pursuits in Greece*. In 1816 the collection was purchased by the nation for £36,000, and placed in the British Museum, the outlay incurred by Lord Elgin having been more than £50,000. Lord Elgin was a Scotch representative peer for fifty years. He died at Paris, November 14, 1841.

ELGIN AND KINCARDINE, James Bruce, Earl of (1811–1863), was the eighth earl of Elgin and twelfth earl of Kincardine in the peerage of Scotland, and the first Baron Elgin in that of the United Kingdom. The eldest son of Thomas, the seventh earl, by his second marriage, he was born in 1811, and succeeded to the peerage in 1841. He was educated at Eton and at Christ Church, Oxford, where he had as companions and rivals his younger predecessors in the office of governor-general of India, Dalhousie and Canning. Mr. Gladstone also was one of his juniors at both school and college, and recalls the circumstance that it was from young Bruce he "first learned that Milton had written any prose." As a young man he came into contact with Dr. Chalmers, who induced him to speak in public on church extension, and it was to Chalmers's sermon on the "Expulsive Power of a New Affection" that he turned on his death-bed, repeating many passages from it in the last hour. He sat in the House of Commons for Southampton long enough to attach him to the constitutional principles now described as Liberal-Conservative, though he never identified himself with a party.

Lord Elgin began his official career in 1842, at the age of thirty, as governor of Jamaica. He succeeded the great Indian civilian, Lord Metcalfe, who had left the colony in such a state of quietude and prosperity as was possible soon after emancipation. During an administration of four years he succeeded in winning the respect of all classes. He improved the condition of the negroes and conciliated the planters by working through them. In 1846 Lord Grey appointed him governor-general of Canada. Son-in-law of the popular earl of Durham, he was well received by the colonists, and he set himself deliberately to carry out the policy which makes Lord Durham's name remembered there with gratitude to this day. Alike from his political experience in England and his life in Jamaica Lord Elgin had learned that safety lay in acting as the moderator of all parties, while applying fearlessly the constitutional principles of the mother country to each difficulty as it arose. In this his frank and genial manners also aided him powerfully. His assent to the local measure for indemnifying those who had suffered in the troubles of 1837 led the mob of Montreal to pelt his carriage for the rewarding of rebels for rebellion, as Mr. Gladstone described it. But long before his eight years' term of service expired he was the most popular man in Canada. His relations with the United States, his hearty support of the self-government and defence of the colony, and his settlement of the free-trade and fishery questions, moreover, led to his being raised to the British peerage.

Soon after his return to England in 1854, Lord Palmerston offered him a seat in the Cabinet as chancellor of the duchy of Lancaster, which he declined. But when, in 1856, the seizure of the "Arrow" by Commissioner Yeh plunged England into war with China, he at once accepted the appointment of special envoy with the expedition. On reaching Point de Galle he was met by a force summoned from Bombay to Calcutta by the news of the sepoy mutiny at Meerut on the 11th May. His first idea, that the somewhat meagre intelligence would justify most energetic action in China, was at once changed when urgent letters from Lord Canning reached him at Singapore, the next port, on the 3d June. H.M.S. "Shannon" was at once sent on to Calcutta with the troops destined for China, and Lord Elgin himself followed it when gloomier letters from India reached him. The arrival of the "Shannon" gave new life to the handful of white men fighting for civilization against fearful odds, and before the reinforcements from England arrived the back of the mutiny had been broken. Nor was the position in China seriously affected by the want of the troops. Lord Elgin sent in his ultimatum to Commissioner Yeh at Canton on the same day, the 12th December, that he learned the relief of Lucknow, and he soon after sent Yeh a prisoner to Calcutta. By July, 1858, after months of Chinese deception, he was able to leave the Gulf of Pecheli with the emperor's assent to the Treaty of Tiensin, whereby concessions were made such as all civilized peoples grant to each other, if only from self-interest. The treaty sanctions the residence of foreign ambassadors in Peking—long secured by the Russians—guarantees protection to Christians, opens the country to travellers with passports, and the Yang-tzse and five additional ports to trade, under a revised tariff. The sum of £650,000 was exacted for losses at Canton, and an equal sum for the expenses of the war. Following the Americans, the apparently successful plenipotentiary visited Japan, and obtained less considerable concessions from its Government in the Treaty of Yeddo. It is true that the negotiations were confined to the really subordinate Tycoon or Shogoon, holding an office since abolished, but that visit proved the beginning of British influence in the most progressive country of Asia. Unfortunately, the Chinese difficulty was not yet at an end. After tedious disputes with the tariff commissioners as to the opium duty, and a visit to the upper waters of the Yang-tzse, Lord Elgin had reached England in May, 1859. But when his brother and the allied forces attempted to proceed to Peking with the ratified treaty, they were fired on from the Taku forts at the mouth of the Peiho. The Chinese had resolved to try the fortune of war once more, and Lord Russell again sent out Lord Elgin as ambassador extraordinary to demand an apology for the attack, the execution of the treaty, and an indemnity for the military and naval expenditure. Sir Robert Napier (afterwards Lord Napier of Magdala), and Sir Hope Grant, with the French, so effectually routed the Tatar troops and sacked the Summer Palace that by the 24th October, 1860, a convention was concluded, which was "entirely satisfactory to Her Majesty's Government." The treaty and convention have regulated the relations of China with the West to the present time (1878). In the interval between the two visits to China, Lord Elgin held the office of postmaster-general in Lord Palmerston's administration, and was elected lord rector of the university of Glasgow. He had not been a month at home after the second visit when the same premier selected him to be Her Majesty's viceroy and governor-general of India.

Lord Elgin had now attained the object of his honorable ambition, after the office had been filled in most critical times by his juniors and old college companions, the marquis of Dalhousie and the Earl Canning. He succeeded a statesman who had done much to reorganize the whole administration of India, shattered as it had been by the mutiny. Long, too long in grappling with it, as he himself afterwards confessed, Lord Canning had atoned for the sluggishness of his early action by the vigor of his last two years of office, and established his popularity on the firm basis of his land-tenure reforms and his foreign or feudatory policy. Lord Elgin could only develop both, and he recognized this as what he called his "humble task." But, as the first viceroy directly appointed by the Crown, and as subject to the secretary of state for India, Lord Elgin at once gave up all Lord Canning had fought for, in the co-ordinate independence, or rather the stimulating responsibility, of the governor-general, which had prevailed from the days of Clive and Warren Hastings. From his time to the present the old powers of the historic governor-general have been overshadowed by the party influences of the Indian secretary. This subservience was seen in a further blow at the legislature, by which a bill could be published without leave from the Calcutta council, and in the reversal of Lord Canning's measure for the sale of a fee-simple tenure with all its political as well as economic advantages. But, on the other hand, Lord Elgin loyally carried out the wise and equitable policy of his predecessor towards our feudatories with a firmness and a dignity that in the case of Holkar and Oudeypore had a good effect. He did his best to check the aggression of the Dutch in Sumatra, which was contrary to treaty, and he supported Dost Mahomed in Cabul until that aged warrior entered the then neutral and disputed territory of Herat. Determined to maintain inviolate the integrity of our own north-west frontier, Lord Elgin assembled a camp of exercise at Lahore, and marched a force to the Peshawur border to punish those branches of the Yusufzai tribe who had violated the engagements of 1858.

It was in the midst of this "little war" that he died. Soon after his arrival at Calcutta, he had projected the usual tour to Simla, to be followed by an inspection of the Punjab and its warlike ring-fence of Pathans. He even contemplated the summoning of the central legislative council at Lahore. After passing the summer of 1863 in the cool retreat of Peterhoff, Lord Elgin began a march across the hills from Simla to Sealkote by the upper valleys of the Beas, the Ravee, and the Chenab, chiefly to decide the two allied questions of tea cultivation and trade routes to Kashgaria and Tibet. The climbing up to the Rotung Pass (13,000 feet) which separates the Beas valley from that of the Chenab, and the crossing of the frail twig bridge across the Chundra torrent, prostrated him by the time he had descended into the smiling English-like Kangra valley. Thence he wrote his last letter to Sir Charles Wood, still full of hope and not free from anxiety as to the Sittana expedition. At the lovely hill station of Dhurmsala, "the place of piety," he lay on his death-bed, watching the glories of the Himalayan autumn, and even directing Lady Elgin where to select his grave in the little cemetery around the station church, which hangs high on the bluff above the house where he breathed his last. After telegraphing his resignation to the Queen, he lay for a fortnight amid sacred words and holy thoughts, tended by loving and skilful hands, and suddenly gave up the fight with agony on the 20th November, 1863. He died of fatty degeneration of the muscular fibre of the heart. He is the second governor-general whose body has a resting place in India, Lord Cornwallis having found a grave at Ghazeepore, during his second administration. It is vain to speculate what Lord Elgin might have been had he lived to apply the experience gathered during his eventful apprenticeship to Indian administration. Sir John (now Lord) Lawrence, the great Bengal civilian, took up his task. Lord Elgin will be best remembered as the quietly successful governor-general of Canada for eight years.

For his whole career see *Letters and Journals of James, Eighth Earl of Elgin* (John Murray), edited by Walrond, but corrected by his brother-in-law, Dean Stanley; for the China missions see *Narrative of the Earl of Elgin's Mission to China and Japan*, by Laurence Oliphant, his private secretary; for the brief Indian administration see the *Friend of India* for 1862–63. (G. SM.)

EL-GOLEA, a town on the southern frontiers of Algeria, in that part of the Sahara which bears the name of El-erg, about 160 miles S. W. of Wargla, in 30° 35′ N. lat. and 3° 10′ E. lon. It consists of three portions—the citadel on a limestone hill, the upper town, and the lower town, each separated from the others by irregular plantations of date trees. In itself it is of no particular interest, but its position makes it a very important station for the caravan trade between Algeria and the countries to the south. It was originally a settlement of the Zenâta Berbers, by whom it was known as Taorert; and there is still a considerable Berber element in its population, though the Arabic language is in general use. The full Arab name is *El Golea'a el Menia'a*, or the "little fortress well defended." According to the statement of the natives, the well in the upper town is about 60 feet deep.

ELI (1 Sam. chaps. i.–iv.) was priest of Jehovah at the temple of Shiloh, the sanctuary of the ark, and at the same time judge over Israel—an unusual combination of offices, which must have been won by signal services to the nation in his earlier years, though in the history preserved to us he appears in the weakness of extreme old age, unable to control the petulance and rapacity of his sons, Hophni and Phinehas, which disgraced the sanctuary and disgusted the people. While the central authority was thus weakened, the Philistines advanced against Israel, and gained a complete victory in the great battle of Ebenezer, where the ark was taken, and Hophni and Phinehas slain. On hearing the news, Eli fell from his seat and died. According to the Massoretic text, he was ninety-eight years old, and had judged Israel for forty years (1 Sam. iv. 15, 18). The Septuagint translator gives but twenty years in ver. 18, and seems not to have read ver. 15 [Wellhausen *in loco*]. After these events the sanctuary of Shiloh appears to have been destroyed by the Philistines [comp. Jer. vii.; Ewald, *Geschichte*, ii. 584; Wellhausen on 2 Sam. viii. 17], and the descendants of Eli with the whole of their clan or "father's house" subsequently appear as settled at Nob (1 Sam. xxi. 1, xxii. 11 *sqq.*, comp. xiv. 3). In the massacre of the clan by Saul, with the subsequent deposition of the survivor Abiathar from the priestly office (1 Kings ii. 27), the prophecies of judgment uttered in the days of Eli against his corrupt house were strikingly fulfilled (1 Sam. ii. 27 *sqq.*, iii. 11 *sqq.*).[1]

An important point of Hebrew archæology is involved in the genealogy of Eli and his house. It appears from 1 Kings ii. 27–35 that Zadok, from whom the later high priests claimed descent, and who appears in 1 Chron. v. 38 (E. V. vi. 12) as the lineal descendant of Aaron through Eleazar and Phineas, was not of the house of Eli, and in 1 Chron. xxiv. Ahimelech, son of Abiathar, is reckoned to the sons of Ithamar, the younger branch of the house of Aaron. Hence the traditional view that in the person of Eli the high-priesthood was temporarily diverted from the line of Eleazer and Phinehas into that of Ithamar [comp. Joseph. *Ant.* c. 11, § 5, v. viii. c. 1, § 3, and for the fancies of the Rabbins on the cause of this diversion, Selden, *De Succ. in Pontif.*, lib. i. cap. 2]. This view, however, seems to be absolutely inconsistent with 1 Sam. ii., which represents Eli's "father's house" or clan as the original priestly family, and predicts the destruction or degradation to an inferior position of the whole of this "father's house," and not merely of the direct descendants of Eli. Moreover, Ahimelech, who is the only link to connect Eli with Ithamar, is an ambiguous personage, who, perhaps, owes his existence to a corruption in the text of 2 Sam. viii. 17 [comp. Wellhausen *in loco;* Graf, *Geschichtliche Bücher*, p. 237], where most recent critics read, and the history seems to require, "Abiathar son of Ahimelech" [comp., however, Bertheau on 1 Chron. xviii. 16, and Keil on 1 Chron. v.]. To build an elaborate theory on the genealogical statements in Chronicles is the less justifiable because that book wholly ignores the priesthood of Eli, while Hebrew genealogies must sometimes be understood in a figurative sense. Compare further on the whole subject, Thenius and Wellhausen, on 1 Sam. ii.; Ewald's *Geschichte*, ii. p. 576 *sqq.;* Graf, "Zur Geschichte des Stammes Levi" in Merx's *Archiv*, i. pp. 79, 88, and among older writers especially Selden, in his book already cited, *De Successione in Pontificatum*. (W. R. S.)

ELIAS LEVITA (1472–1549), a Jewish rabbi, the most distinguished Hebrew scholar of his time, was born at Neustadt, on the Aisch, in Bavaria, in 1472. From the fact that he spent most of his life in Italy, some have supposed him to have been an Italian by birth. There can be no doubt, however, that he was a German, as he asserts the fact in the preface to one of his works, and his pupil Münster states expressly that he was born at Neustadt of Jewish parents. His father, Rabbi Ascher Levita, assumed the surname of Aschkenasi (the German), which was also used by the son. Banished as a Jew from his native country, Elias went to Italy in the beginning of the 16th century. He resided at first in Venice, where he earned a high reputation as a teacher of Hebrew. In 1504 he removed to Padua, where he continued his career as a teacher, and wrote a commentary on the Hebrew grammar of Rabbi Kimchi. When Padua was sacked in 1509 he lost all his property, and removed to Venice. About 1512 he took up his residence in Rome, where he enjoyed for a number of years the friendship of Cardinal Egidio, and of several other dignitaries of the church. So intimate were his relations with the Christians that he was accused of having apostatized from Judaism. His opinions were undoubtedly more liberal than those of the majority of the Jews of his time, but there is no reason to question his own assertion that he remained true to the faith in which he was born. When Rome was attacked by Charles V. in 1527, Elias Levita lost all his means for the second time, and again found an asylum in Venice. In 1540 he went to Isny in Swabia, having been invited by Paul Fagius to join him in the superintendence of a printing-press for Hebrew books. The last two years of his life were spent in Venice, where he died in 1549. The most valuable of the numerous works of Elias Levita were those bearing on Hebrew grammar and lexicography. His *Massoreth Hammassoreth* (Venice, 1538) is a critical commentary on the text of the Hebrew Scriptures, and contains a very able discussion of the question of the origin of the vowel points, which he assigns to the Massoretic doctors of the school of Tiberias in the 5th century after Christ. He also wrote a treatise on Hebrew grammar, a dictionary, chiefly to the Targums and the Talmud, and several smaller works in Hebrew philology. In the preface to his *Massoreth*, and other portions of his works, there are various autobiographical details. A German translation of the *Massoreth Hammassoreth* by Semler appeared in 1772, and an edition of the work with notes and an English translation was published in London in 1867.

ÉLIE DE BEAUMONT, JEAN BAPTISTE ARMAND LOUIS LÉONCE (1798–1874), a celebrated French geologist, was born at Canon, in Calvados, on the 25th September, 1798. He was educated at the Lycée Henri IV., where he took the first prize in mathematics and physics; at the École Polytechnique, where he stood first at the exit examination in 1819; and at the École des Mines, where he began to show a decided preference for the science with which his name is associated. In 1823 he was selected along with Dufrénoy by Brochant de Villiers, the professor of geology in the École des Mines, to accompany him on a scientific tour to England and Scotland, with the double object of inspecting the mining and metallurgical establishments of the country, and of studying the principles on which the geological map of England had been prepared, with a view to the construction of a similar map of France. An account of the tour was published by Élie de Beaumont and Dufrénoy conjointly, under the title *Voyage métallurgique en Angleterre* (1827). In 1835 he was appointed professor of geology at the École des Mines, in succession to Brochant de Villiers, whose assistant he had been in the duties of the chair since 1827. He held the office of engineer-in-chief of mines in France from 1833. His growing scientific reputation secured his election to the membership of the Academy of Berlin, of the Academy of Sciences of France, and of the Royal Society of London. By a decree of the president he was made a senator of France in 1852, and on the death of Arago (1853) he was chosen perpetual secretary of the Academy of Sciences. Élie de Beaumont's name is best known to geologists in connection with his theory of the origin of mountain ranges, first propounded in a paper read to the Academy of Sciences in 1829, and afterwards elaborated in several treatises and shorter papers, of which the *Notice sur le système des montagnes* (3 vols., 1852) may be named as the most important. According to his view, all mountain ranges parallel to the same great circle of the earth are of strictly contemporaneous origin, and between the great circles a relation of symmetry exists in the form of a pentagonal *réseau.* For an elaborate statement and criticism of the theory, see the introductory address by Hopkins in the *Journal of the Geological Society of London* for 1853. The theory has not found general acceptance, but it has proved of great value to geological science, owing to the extensive additions to the knowledge of the structure of mountain ranges which its author made in endeavoring to find facts to support it. Probably, however, the best service Élie de Beaumont rendered to science was in connection with the geological map of France, in the preparation of which, from 1825 till its completion eighteen years later, he had the leading share. After his compulsory superannuation at the École des Mines, he continued to superintend the issue of the detailed maps almost until his death, which occurred on the 21st September, 1874. His academic lectures for 1843–44 were published in 1847 under the title *Leçons de Géologie Pratique.*

---

[1] A curious Jewish tradition makes Phinehas the man of God who denounced judgment on Eli. Jerome, *Quæst. Heb. in Lib. I. Regum.*

ELIJAH (ELIJAHU, literally *God-Jehovah;* in N. T., ELIAS), the greatest and sternest of the Hebrew prophets, makes his appearance in the narrative of the Old Testament with an abruptness that is strikingly in keeping with his character and work. The words in which he is first introduced—"Elijah the Tishbite, of the inhabitants of Gilead" (1 Kings xvii. 1)—contain all that is told of his origin, and, few as the words are, their meaning is not without ambiguity. By varying the pointing of the Hebrew word translated "of the inhabitants" in the authorized version, the passage is understood by a number of critics to indicate a Tishbeh in Gilead, not named elsewhere, as the birthplace of the prophet; but it is not certain that anything more definite is meant than that the prophet came from Gilead, the mountainous region beyond Jordan. Whether the place of his birth is definitely indicated or not, there is nothing said of his genealogy; and thus his unique position among the prophets of Israel, whose descent is almost invariably given, is signalized from the first. Some have supposed that he was by birth a heathen and not a Jew, but this is an unfounded conjecture, so inherently improbable that it does not deserve consideration. His appearance in the sacred narrative, like Melchisedek, "without father, without mother," gave rise to various rabbinical traditions, such as that he was Phinehas,[1] the grandson of Aaron, returned to earth, or that he was an angel in human form.

The first and most important part of Elijah's career as a prophet lay in the reign of Ahab, which, according to the usual chronology, commenced about 918 B.C. He is introduced in the passage already quoted (1 Kings xvii. 1) as predicting the drought God was to send upon Israel as a punishment for the apostasy into which Ahab had been led by his heathen wife Jezebel. The duration of the drought is vaguely stated in Kings; from Luke iv. 25 and James v., 17, we learn that it lasted three years and a half. During the first portion of this period Elijah, under the divine direction, found a refuge by the brook Cherith, "before the Jordan." This description leaves it uncertain whether the brook was to the east of Jordan in Elijah's native Gilead, or to the west in Samaria, as Robinson supposes. Here he drank of the brook and was fed by ravens, who night and morning brought him bread and flesh. The word translated "ravens" has also been rendered "merchants," "Arabians," or "inhabitants of the rock Oreb." There is a general concurrence of opinion, however, that the authorized version represents the true sense of the original. When the growing severity of the drought had dried up the brook, the prophet, under the same divine direction as before, betook himself to another refuge in Zarephath, a Phœnician town near Zidon. At the gate of the town he met the widow to whom he had been sent gathering sticks for the preparation of what she believed was to be her last meal. Though probably a worshipper of Baal, she received the prophet with hospitality, sharing with him her all but exhausted store, in faith of his promise in the name of the God of Israel that the supply would not fail so long as the drought lasted. Her faith was rewarded by the fulfilment of the promise, the cruse of oil and the barrel of meal affording sustenance for both herself and her guest until the close of the three and a half years' famine. During this period her son died, and was miraculously restored to life in answer to the prayers of the prophet.

Elijah emerged from his retirement in the third year, when, the famine having reached its worst, Ahab and his minister Obadiah had themselves to search the land for provender for the royal stables. To the latter Elijah appeared with his characteristic suddenness, and announced his intention of showing himself to Ahab. The king, who in spite of the calamity that had befallen him, was still hardened in his apostasy, met Elijah with the reproach that he was the troubler of Israel, which the prophet with the boldness that befitted his mission at once flung back upon him who had forsaken the commandments of the Lord and followed the Baalim. The retort was accompanied by a challenge—or rather a command—to the king to assemble on Mount Carmel "all Israel" and the four hundred and fifty prophets of Baal and the four hundred prophets of Asherah. The latter are described as "eating at Jezebel's table," by which it is indicated that they were under the special favor and protection of the queen. From the allusion to an "altar of Jehovah that was broken down" (1 Kings xviii. 30) it has been inferred that Carmel was an ancient sacred place, though this is the first mention of it in the Scripture narrative. (On Mount Carmel and Elijah's connection with it in history and tradition see CARMEL, vol. v. p. 103.)

The scene on Carmel is perhaps the grandest in the life of Elijah, or indeed in the whole of the Old Testament. As a typical embodiment for all time of the conflict between superstition and true religion, it is lifted out of the range of mere individual biography into that of spiritual symbolism, and it has accordingly furnished at once a fruitful theme for the religious teacher and a lofty inspiration for the artist. The incident is indeed a true type, showing the characteristic features of combatants that are always meeting, and of a conflict that is always being waged. The false prophets were allowed to invoke their god in whatever manner they pleased from the early morning until the time of evening sacrifice. The only interruption came at noon, in the mocking encouragement of Elijah (1 Kings xviii. 27), which is remarkable as an almost solitary instance of grim sarcastic humor occurring in the Bible. Its effect upon the false prophets was to increase their frenzy; they "cried aloud and cut themselves with knives and lancets," as the authorized version has it. The translation should rather be "swords and lances." The evening came, and the god had made no sign; "there was neither voice, nor any to answer, nor any that regarded." Elijah now stepped forward with the quiet confidence and dignity that became the prophet and representative of the true God. Two things are noteworthy in his preparations: all Israel is represented symbolically in the twelve stones with which he built the altar; and the water poured upon the sacrifice and into the surrounding trench was evidently designed to prevent the suspicion of fraud. In striking contrast to the unreasoning frenzy and the "vain repetitions" of the false prophets are the few and simple words with which Elijah makes his prayer to Jehovah. Once only with the calm assurance of one who knew that his prayer would be answered, he invokes the God of his fathers to vindicate himself in the presence of an apostate people. The answer comes at once: "The fire of the Lord fell and consumed the burnt sacrifice, and the wood, and the stones, and the dust, and licked up the water that was in the trench." So convincing a sign was irresistible; the people who had stood by in wondering silence now fell on their faces and acknowledged Jehovah as the true God. In harmony with the method in which Jehovah often vindicated himself in the Old Testament economy, the acknowledgment of the true prophet and his God was immediately followed by the destruction of the false prophets. The first heat of conviction made the people quick to obey the command to seize the prophets of Baal, who were immediately afterwards slain by Elijah beside the brook Kishon. The deed, though not without parallel in the Old Testament history, stamps the peculiarly vindictive character of Elijah's prophetic mission.

---

[1] *Cf.* Selden, *De Success. in Pont. Heb.* lib. ii. cap. 2.

The people having returned to their rightful allegiance to the true God, the drought sent as a punishment for their defection at once ceased. The narrative proceeds without a break. On the evening of the day that had witnessed the decisive contest, Elijah, after having invited Ahab to eat and drink, and foretold abundance of rain, proceeded once more to the top of Carmel, and there, with "his face between his knees" (possibly engaged in the prayer referred to in James v. 17, 18), waited for the long-looked-for blessing. His servant, sent repeatedly to search the sky for signs, returned the seventh time reporting a little cloud arising out of the sea "like a man's hand." The portent was scarcely seen ere it was fulfilled. The sky was full of clouds and a great rain was falling when Ahab, obeying the command of Elijah, set out in his chariot for Jezreel. Elijah, with what object does not appear, ran before the chariot to the entrance of Jezreel, a distance of at least sixteen miles, thus showing the power of endurance natural to a prophet of the wilderness. If he went with any hope that the events that had just occurred would change the heart of Jezebel, as they seem to have changed the heart of the king, he was at once undeceived. On being told what had taken place, Jezebel sent a messenger to Elijah with a vow in the most solemn terms that ere another day had passed his life would be even as the lives of the prophets of Baal, and the threat was enough to cause him to take to instant flight.

The first stage of his journey was to Beersheba, on the confines of the kingdom of Judah. Here he left his servant, who, according to an old Jewish tradition, was the widow's son of Zarephath, afterwards the prophet Jonah,[1] and proceeded a day's journey into the wilderness. Laying himdown under a solitary juniper (broom), he gave vent to his bitter disappointment at the apparent failure of his efforts for the reformation of Israel in a prayer for death. By another of those miraculous interpositions which occur at nearly every turn of his history he was twice supplied with food and drink, in the strength of which he journeyed forty days and forty nights until he came to Horeb, where he lodged in a cave. A hole "just large enough for a man's body" (Stanley), immediately below the summit of Jebel Mûsa, is still pointed out by tradition as the cave of Elijah.

If the scene on Carmel was the grandest, that on Horeb was spiritually the most profound in the life of Elijah. There for the first time he learned that the normal channel of divine revelation is spiritual and not material, and that its object is mercy and not judgment. Not in the strong wind that brake the rocks in pieces, not in the earthquake, not in the fire, but in the still small voice that followed, the Lord made himself known. There, too, he learned, also for the first time, the true nature and limits of his own prophetic mission. He was the herald, not of a sudden vengeance and a sudden reformation of which his own eyes might hope to see the fulfilment, but of the slow steady progress of that kingdom of God that cometh not with observation. He was taught this practically in the threefold commission laid upon him, which implied in each part of it that the work of vengeance and of reformation alike were to be fulfilled by other hands and in a succeeding age. He was to return to Damascus and anoint Hazael king of Syria; he was to anoint Jehu the son of Nimshi as king of Israel in place of Ahab; and as his own successor in the prophetic office he was to anoint Elisha the son of Shaphat. The revelation at Horeb closed with an announcement that must have been at once a comfort and a rebuke to the prophet. In his allegiance to Jehovah he was not alone, as in sadness of spirit he had supposed; there were no less than seven thousand in Israel who had not bowed to Baal.

Leaving Horeb and proceeding northwards, Elijah found the opportunity of fulfilling the last of the three commands that had been laid upon him. He met Elisha engaged at the plough probably near his native place, Abel-meholah, in the valley of the Jordan, and, by the symbolical act of casting his mantle upon him, consecrated him to the prophetic office. As it happened, this was the only command of the three which he fulfilled in person; the course of events left the other two to be carried out by his successor. After the call of Elisha the narrative contains no notice of Elijah for several years. It was not until Ahab, at the prompting of Jezebel, had committed his crowning iniquity in the matter of Naboth's vineyard that he again appeared, as usual with startling abruptness. Without any indication of whence or how he came, he is represented in the narrative as standing in the vineyard when Ahab entered to take possession of it, and as pronouncing upon the king and his house that awful doom (1 Kings xxi. 17–24) which, though deferred for a time, was ultimately fulfilled to the letter.

With one more denunciation of the house of Ahab, Elijah's function as a messenger of wrath was fully discharged. When Ahaziah, the son and successor of Ahab, having injured himself by falling through a lattice, sent to inquire at Baal-zebub, the god of Ekron, whether he should recover, the prophet was commanded by God to appear to the messengers and tell them that, for this resort to a false god, the king should die. The effect of his appearance was such that they turned back without attempting to fulfil their errand. Their description of the prophet left the king in no doubt as to his identity: "It is Elijah the Tishbite." With the true Jezebel spirit he resolved to destroy the enemy of his house, and despatched a captain with a band of fifty to arrest him. They came upon Elijah seated on "the mount,"—probably Carmel. The imperious terms in which he was summoned to come down—perhaps also a tone of mockery in the appellation "Thou man of God"—were punished by fire from heaven, which descended at the bidding of Elijah and consumed the whole band. A second captain and fifty were despatched, behaved in a similar way, and met the same fate. The leader of a third troop took a humbler tone, sued for mercy, and obtained it. Elijah then went with them to the king, but only to repeat before his face the doom he had already made known to his messengers, which was almost immediately afterwards fulfilled.

The only mention of Elijah's name in the book of Chronicles (2 Chron. xxi. 12–15), where he is represented as sending a letter of rebuke and denunciation to Jehoram, king of Judah, furnishes a chronological difficulty, owing to the fact that Elijah's translation seems to have taken place before the death of Jehoshaphat, the father of Jehoram. There is reason, however, to suppose that Jehoram reigned for some years before the death of his father; and on the other hand, though the account of Elijah's translation (2 Kings ii.) immediately follows that of his last public act in denouncing the doom of Ahaziah (2 Kings i.), a considerable interval may have elapsed between the two events. Whatever its duration, the time was spent in close and continuous fellowship with Elisha, his disciple and successor, who, though thrice entreated to leave him, showed the true disciple spirit in the solemn vow, "As the Lord liveth, and as thy soul liveth, I will not leave thee." The approaching translation seems to have been known, not only to Elijah and Elisha, but also to the schools of the prophets at Bethel and Jericho, both of which they visited in their last eastward journey. At the Jordan their progress was stopped only until Elijah, wrapping his prophet's mantle together, smote the water with it, and so by a last miracle passed over on dry ground. When they had crossed, the master desired the disciple to ask some parting blessing. The request for a double portion (*i.e.*, probably a first-born's portion) of the prophet's spirit Elijah characterized as a hard thing; but he promised to grant it if Elisha should remain with him to the last, so as to see him when he was taken away. The end is told in words of simple sublimity: "And it came to pass, as they still went on and talked, that, behold, there appeared a chariot of fire, and horses of fire, and parted them both asunder; and Elijah went up by a whirlwind into heaven" (2 Kings ii. 11). There is in this, as Stanley has truly remarked, an "inextricable interweaving of fact and figure." It is scarcely necessary to point out, however, that through the figure the narrative evidently means to convey as fact that Elijah passed from earth, not by the gates of death, but by miraculous translation. Such a supernatural close is in perfect harmony with a career into every stage of which the supernatural enters as an essential feature. For whatever explanation may be offered of the miraculous element in Elijah's life, it must obviously be one that accounts not for a few miraculous incidents only, which might be mere excrescences, but for a series of miraculous events so closely connected and so continuous as to form the main thread of the history.

---

[1] Jerome, *Prooem. in Jonam.*

Elijah occupied an altogether peculiar place in later Jewish history and tradition. Of the general belief among the Jewish people that he should return for the restoration of Israel the Scriptures contain several indications, such as the prophecy of Malachi (iv. 5, 6). Even if this be applied to John the Baptist, between whom and Elijah there are many striking points of resemblance, there are several allusions in the gospels which show the currency of a belief in the return of Elias, which was not satisfied by the mission of John (Matt. xi. 14, xvi. 14; Luke ix. 8; John i. 21).[1]

Elijah is canonized both in the Greek and in the Latin Churches, his festival being kept in both on the 20th July,—the date of his ascension in the nineteenth year of Jehoshaphat, according to Cornelius a Lapide. (W. B. S.)

ELIOT, John (1604–1690), "the Apostle of the Indians of North America," was born at Nasing, in Essex, in 1604, and was educated at Jesus College, Cambridge, where he took his bachelor's degree in 1623. He there displayed a partiality for philology which may have had some influence in stimulating the zeal he afterwards displayed in acquiring the language of the native Indians. After leaving the university he was employed as an usher in a school near Chelmsford under the Rev. Thomas Hooker. While in the family of Mr. Hooker, Eliot received serious impressions, and resolved to devote himself to the work of the Christian ministry. As there was then no field for nonconformist preachers in England, he resolved to emigrate to America, where he arrived on the 3d of November, 1631. After officiating for a year in the first church in Boston, he was in November, 1632, appointed pastor of the church in Roxbury, where he continued till his death.

When Eliot began his mission work there were about twenty tribes of Indians within the bounds of the plantation of Massachusetts Bay, and for a long time he assiduously employed himself in learning their language. He obtained the assistance of a young Indian taken prisoner in the Pequot war of 1637, and who had been put to service with a Dorchester planter. With his help Eliot translated the Commandments, the Lord's Prayer, and many Scripture texts, and at length was able to preach to the Indians in their own language. This he did without the aid of an interpreter in 1646, at a place a few miles from Cambridge, afterwards called Nonantum or Noonatomen, *i.e.*, "Rejoicing," where a settlement of Christian Indians was subsequently established.

The labors of Eliot, being reported in England, excited great attention, and a society, afterwards incorporated, was instituted for the propagation of the gospel in New England. Among its leading members was the Hon. Robert Boyle, well known by his scientific labors, who was one of Eliot's constant correspondents. From the funds of this corporation an allowance of £50 per annum was paid to Eliot in supplement of his moderate salary of £60 as minister of Roxbury.

In 1651 a town called Natick, or "Place of Hills," was founded by the Christian Indians, mainly through the instrumentality of Eliot, for which he drew up a set of civil and economical regulations. He also in 1653, at the charge of the corporation, published a catechism for their use. This was the first work published in the Indian language; no copy of it is known to exist. In the same year there was published by the corporation in London a work called *Teares of Repentance, or a further Progress of the Gospel among the Indians of New England*, in which there was given "A Brief Relation of the Proceedings of the Lord's Work among the Indians, in reference unto their Church-estate, by John Eliot."

In 1655 there was published in London by the corporation a tract entitled *A Later and Further Manifestation of the Progress of the Gospel amongst the Indians in New England, declaring their Constant Love and Zeal to the Truth, etc., being a Narrative of the Examinations of the Indians about their Knowledge in Religion by the Elders of the Church, related by Mr. John Eliot.* This work contained the confessions of those Indians that were baptized by Eliot and admitted to church fellowship. In 1660 Eliot drew upon himself some animadversion by the publication at London of a work called *The Christian Commonwealth, or the Civil Policy of the rising Kingdom of Jesus Christ*, which was found to contain seditious principles, especially directed against the Government of England. The statements, however, made in this book were afterwards retracted by its author.

About this time Eliot completed his task of translating the Bible into the Indian language. The corporation in London supplied the funds, and the New Testament in Indian was issued in 1661, shortly after the restoration of Charles II. It happened that the printing of the work was completed when the corporation was expecting a royal charter. A dedication to the king was accordingly inserted, written in a tone calculated to win his favor. It stated that the Old Testament was in the press, and it craved the "royal assistance for the perfecting thereof." The Old Testament was at length published in 1663. Copies of the New Testament were bound with it, and thus the whole Bible was completed in the Indian language. To it were added a catechism, and the Psalms of David in Indian verse. The title of this Bible, which is now of great rarity, and fetches a very high price, is *Mamussee Wunneetupanatamwe Up-Biblum God naneeswe Nukkone Testament kah wonk Wusku Testament—Ne quoshkinnumuk nashpe Wuttinneumoh Christ noh asoowesit John Eliot;* literally translated:—"The whole Holy his-Bible God, both Old Testament and also New Testament. This turned by the servant-of-Christ, who is-called John Eliot." This Indian version of the Scriptures was printed at Cambridge (U.S.) by Samuel Green and Marmaduke Johnson, and was the first Bible printed in America.

In 1680 another edition of the New Testament was published; and in 1685 the second edition of the Old Testament appeared. This last was bound up with the second impression of the New Testament, and the two parts form the second edition of the whole Bible. It was dedicated "To the Hon. Robert Boyle, the Governour, and to the Company for the Propagation of the Gospel," etc., and is, like the first edition, a work of great rarity. Eliot received valuable assistance in preparing this edition from the Rev. John Cotton of Plymouth (U.S.), who had also spent much labor in obtaining a thorough knowledge of the Indian language. A new edition of the Indian Bible was printed in 1822 at Boston by P. S. Duponceau and J. Pickering.

Besides his translation of the Bible, Eliot published at Cambridge (U.S.) in 1664 a translation of Baxter's *Call to the Unconverted*, of which a second edition was issued in 1688. In 1665 he published an abridged translation of Bishop Bayly's *Practice of Piety*, and a second edition in 1685. His well-known *Indian Grammar Begun* was written in the winter of 1664, his sons assisting in the work, and was printed at Cambridge (U.S.) in 1666. At the end of this book are these memorable words,—"Prayers and pains, through faith in Jesus Christ, will do anything." The grammar was reprinted in 1822, with notes by Pickering and Duponceau, in the *Collections of the Massachusetts Historical Society*, vol. ix. *The Indian Primer; or the Way of Training up of our Indian Youth in the Good Knowledge of God; by J. E.*, was printed at Cambridge (U.S.) in 1669. It comprises an exposition of the Lord's Prayer and a translation of the Larger Catechism in Indian. A reprint of this work, from the only complete copy known to exist, preserved in the library of the university of Edinburgh, was published, under the editorial superintendence of Mr. John Small, in 1877.

In 1671 Eliot printed in English a little volume entitled *Indian Dialogues, for their Instruction in that Great Service of Christ in Calling Home their Countrymen to the Knowledge of God and of themselves.* This was followed in 1672 by *The Logick Primer; some Logical Notions to Initiate the Indians in the Knowledge of the Rule of Reason*, etc. These two volumes, printed at Cambridge (U.S.), are extremely rare. Of the former, the only known copy exists in a private library in New York. A copy of the *Logick Primer* is preserved in the British Museum, and another in the Bodleian.

---

[1] For curious facts indicating the survival of the same belief among the Jews at the present day, see Stanley's *Jewish Church*, lect. xxx.

In 1611 a small tract of eleven pages was published at London, called *A Brief Narrative of the Progress of the Gospel among the Indians in New England in the Year 1670. Given in by the Rev. Mr. John Eliot, Minister of the Gospel there, in a Letter by him directed to the Right Worshipful the Commissioners under His Majesty's Great Seal for the Propagation of the Gospel amongst the Poor Blind Natives in those United Colonies.* This was possibly one of the publications of the corporation after their charter was renewed by Charles II.; it is of extreme rarity.

In his old age the pen of Eliot was not idle. In 1678 he published *The Harmony of the Gospels in the Holy History of the Humiliation and Sufferings of Jesus Christ from his Incarnation to his Death and Burial.* This work, which was printed at Boston, is a life of our Saviour with many illustrative and practical remarks. The last of his publications was his translation into Indian of Shepard's *Sincere Convert*, which he had nearly completed in 1664; this was revised by Grindal Rawson and printed in 1689.

Eliot died at Roxbury on the 20th of May, 1690, at the age of eighty-six. He was acknowledged to have been a man whose simplicity of life and manners, and evangelical sweetness of temper, had won for him all hearts, whether in the villages of the emigrants or in the smoky huts of the natives of New England.

His translation of the Bible and other works composed for the use of the Indians are written in the Mohican dialect, which was spoken by the aborigines of New England. By Eliot and others it was called the Massachusetts language. Although it is no longer read, the works printed in it are valuable for the information they furnish as to the structure and character of the unwritten dialects of barbarous nations. (J. SM.)

ELIOT, Sir John (1592–1632), one of the greatest among the English statesmen of the reign of Charles I., was born at his father's seat at Port Eliot, a small fishing village on the River Tamar, in the month of April, 1592. He was the son of a country gentleman of hospitable habits, and of considerable influence, if we may judge from Eliot's early entrance into public life. Against his youth no fault has been charged except such as was the natural fruit of a fiery but generous temper, and that it was not entirely spent in idle frolic is proved by the considerable scholarship which he attained. At fifteen he entered Exeter College, Oxford; and on leaving the university, he studied law at one of the inns of court. He also spent some months travelling in France, Spain, and Italy, in company, for part of the time, with young George Villiers, afterwards Duke of Buckingham. At the age of twenty he married the daughter of one of his neighbors, a wealthy Cornish gentleman. He was only twenty-two when, in the distinguished company of Pym and Wentworth, he commenced his parliamentary career, and only twenty-seven when he obtained the appointment of vice-admiral of Devon, with large powers for the defence and control of the commerce of the county. It was not long before the characteristic energy with which he performed the duties of his office involved him in difficulties. After many attempts, in 1623 he succeeded, by a clever but dangerous manœuvre, in entrapping the famous pirate Nutt, who had for years infested the southern coast, inflicting immense damage upon English commerce. The issue is noteworthy, both as the event which first opened Eliot's eyes to the corruptness of the Government, and as an example of one of the causes which produced the Great Rebellion. The pirate, having gained powerful allies at court by means of bribery, was speedily permitted to recommence his career of plunder; while the vice-admiral, upon charges which could not be substantiated, was flung into the Marshalsea, and detained there nearly four months.

A few days after his release Eliot was elected member of Parliament for Newport (February, 1624). From the first he perceived that the success of the popular cause required the entire independence of parliament; and his earliest recorded speech was to propose that, as "misreports" were constantly being carried to the king, the deliberations of the House of Commons should be kept strictly secret. In the days of Eliot such a measure would have carried with it advantages of the first importance; and it was only natural that, in his anxiety to make parliament an efficient check upon the crown, he should forget how necessary was the check upon parliament which would thus have been lost.

In the first three parliaments of the reign of Charles I. Eliot was the foremost leader of the House of Commons. The House was at that time rich in great statesmen. Upon its benches sat Pym, Hampden, Selden, Coke, and many other sincere and steadfast patriots. But, though in profoundness of erudition one or two, but only one or two, may have surpassed him, neither in force of genius, in fire and power of oratory, in loftiness and ardor of sentiment, in inflexible firmness of resolution, nor in personal bravery and self-devotion, had he any superior, while in the union of these great qualities which made up his rare and noble character he had no equal. The circumstances of his past life also conduced to fit him for his position. His official intercourse with the duke of Buckingham, and a certain important interview between them, in which the duke had incautiously unveiled his design of governing without parliament should parliament refuse submission, had given him an early and valuable opportunity of gauging the character of the favorite; and a bitter experience had acquainted him with the corruptness of the court. Undeterred by any vestige of personal fear, he dared, in plain and uncompromising language, to expose all the abuses which oppressed the country through innumerable illegal exactions of many kinds and through the venality of the executive; and to point out how it was disgraced abroad by a foreign policy directed by the mere spleen of the favorite, and by the gross mismanagement of every campaign that had been undertaken. He dared to advise parliament to demand an account of the expenditure of the supplies which it had voted, and to refuse further supplies till such an account had been rendered. Nay, he dared even to brave the king's deadliest hatred by naming repeatedly, with direct and sternest invective, the great duke of Buckingham, the all-powerful favorite, as chiefly responsible for the misgovernment of the country. He did not escape unpunished. In 1626, for drawing a bold parallel between Buckingham and Sejanus, he was sent to the Tower; but the House of Commons refused to proceed with any business till he should be released, and, on his release, passed a vote clearing him from fault. In the same year he was confined for a time in the Gatehouse, whence, careless of mere personal considerations, he ventured to petition the king against forced loans. He was also accused of having, in his capacity of vice-admiral, defrauded the duke of Buckingham, who, among his innumerable offices, held that of admiral of Devon, and was supplanted by a creature of the duke's. And, finally, a sentence of outlawry was passed upon him.

But the very fact that he was thus specially singled out for vengeance by the king only increased the confidence reposed in him by the people. In 1628, despite the most strenuous opposition of the court, he was chosen member for his own county of Cornwall; and he resumed his work with undiminished zeal and courage. He at once advised the House to adopt, and firmly to maintain, the only policy which could be effective, namely, to vote no further supplies till they obtained redress of the grievances of which they complained. He joined with Coke, Selden, Littleton, Wentworth, and others in framing the Petition of Right, and, when the first evasive answer was given to that petition, and men scarce knew what to do for wondering at the king's madness and audacity, he fearlessly reviewed the events of the whole reign, and proposed a remonstrance to the king, naming the duke of Buckingham as the cause of the kingdom's wretchedness. And, on the last day of that famous parliament, when Holles and Valentine held the Speaker in the chair by force, it was his voice which read a protest against levying tonnage and poundage and other taxes without consent of parliament, and against the king's encouragement of Arminians and Papists (for it is characteristic both of himself and of his epoch that, though no Puritan, he spoke as strongly against the king's illegal toleration of Papists as against any other of his illegal acts); and also a declaration that whatever minister should "bring in innovation in religion, or seek to extend, or introduce Popery and Armenianism," or should advise illegal methods of raising money, should be considered "a capital enemy to the commonwealth," nay, that whoever even yielded compliance to such illegal demands, should be held accessory to the crime. This was the last speech of that session, and Eliot's last speech of all.

A few days after, parliament having been dissolved, he was summoned, with Selden, Holles, Valentine, and three other members, before the council. When examined he refused to answer for his conduct in parliament anywhere except before parliament; and he was then, with his companions, committed to "close confinement" in the Tower, books and the use of writing materials being strictly denied. This rigorous treatment was maintained for nearly three months, till Charles found it necessary to give way somewhat to the popular feeling which was expressed by libels against the bishops and the lord-treasurer, and by stern warnings addressed to himself. In May the prisoners were taken before the Court of King's Bench, when Eliot simply repeated the protest he had made before the council. The case was put off time after time till the long vacation came without its having been heard. Eliot was now, however, allowed to communicate with his friends, among whom his most constant and valued correspondent was Hampden, to borrow books from Sir Robert Cotton's library, and to employ the tedious hours in writing. He drew up a defence of his conduct, under the title of *An Apology for Socrates*—"*An recte fecerit Socrates quod accusatus non responderit*," and wrote a little book of philosophical meditations, which he called *The Monarchy of Man*, and an account of the first parliament of Charles I., which he describes on the title-page as "a thing that concerns posterity"—*Negotium Posterorum*,—and which is of no slight historical value. In February, 1623, the sentence was at last pronounced, the prisoners being all condemned to a fine; to be imprisoned during the king's pleasure; and not to be released till they had given security for their good behavior, had submitted to the king, and had acknowledged their offences. The largest fine was imposed upon Eliot—a fine of £2000, which, however, he never paid, as he had taken the precaution of securing his property against such an event. Twenty-seven years later this sentence was reversed by parliament, and Eliot's brave assertion of the independence of parliament was confirmed, never to be again questioned.

The confinement of the other prisoners was gradually made less and less strict, till they were at length allowed full liberty; but Eliot's spirit, which no weariness or suffering could conquer, disdained to submit where he held no submission to be due, and for him there was no mercy. After more than a year had passed since he first entered the Tower, and the king's hate had only increased in malignity, on December 21, 1631, the council met to devise new means to subdue his constancy and force him to submission. All admittance to him was now denied except to his sons. Moved into a room which his letters describe as dark, cold, and wretchedly uncomfortable, at length his health gave way, and the doctors prescribed fresh air and exercise. He now addressed the king, having been referred to him by the Court of King's Bench, to which he had first applied, in a petition, written in simple, manly language, requesting that, for his health's sake, he might be allowed a temporary release. The answer being that the petition was not sufficiently humble, he expressed himself "heartily sorry that he had displeased His Majesty," but merely repeated his request with no word of submission. To this no reply was given; and fifteen days after Sir John Eliot had died in the Tower (27th November, 1632). His sons humbly begged leave to carry his body to Port Eliot, that he might rest with his fathers, but even this poor request Charles had not magnanimity enough to grant; and, by his express command, Sir John Eliot was "buried in the church of the parish where he died."

An excellent life of Sir John Eliot, founded upon elaborate study of his papers and of the history of the period, has been written by John Forster. (T. M. W.)

ELIS, or **ELEIA**, a country of the Peloponnesus, bounded on the N. by Achaia, E. by Arcadia, S. by Messenia, and W. by the Ionian Sea. The local form of the name was Valis, or Valeia, and its meaning, in all probability, the lowland. In its physical constitution Elis is practically one with Achaia and Arcadia; its mountains are mere offshoots of the Arcadian highlands, and its principal rivers are fed by Arcadian springs. From Erymanthus in the north, Skollis (now known as Mavri and Santameri in different parts of its length) stretches toward the west, and Pholoe along the eastern frontier; in the south a prolongation of Mount Lycæon bore in ancient times the names of Minthe and Lapithus, which have given place respectively to Alvena and to Kaiapha and Smerna. These mountains are well clothed with vegetation, and present a soft and pleasing appearance in contrast to the picturesque wildness of the parent ranges. They gradually sink towards the east and die off into what was one of the richest alluvial tracts in the Peloponnesus. Except where it is broken by the rocky promontories of Chleonatas (now Chlemutzi) and Ichthys (now Katakolo), the coast lies low, with stretches of sand in the north and lagoons and marshes towards the south. During the summer months, communication with the sea being established by means of canals, these lagunes yield a rich harvest of fish to the inhabitants, who at the same time, however, are almost driven from the coast by the swarms of gnats.

Elis was divided into three districts—Hollow or Lowland Elis (ἡ κοιλη Ἦλις), Pisatis, or the territory of Pisa, and Triphylia, or the country of the three tribes. Hollow Elis, the largest and most northern of the three, was watered by the Peneus and its tributary the Ladon, whose united stream forms the modern Gastuni. It included not only the champaign country originally designated by its name, but also the mountainous region of Acrorea, occupied by the offshoots of Erymanthus. Besides the capital city of Elis, it contained Cyllene, an Arcadian settlement on the sea-coast, whose inhabitants worshipped Hermes under the phallic symbol, Pylus at the junction of the Peneus and the Ladon, which, like so many other places of the same name, claimed to be the city of Nestor, and the fortified frontier town of Lasion, the ruins of which are still visible at Kuti, near the village of Kumani. The district was famous in antiquity for its cattle and horses; and its byssus, supposed to have been introduced by the Phœnicians, was inferior only to that of Palestine. Pisatis extended south from Hollow Elis to the right bank of the Alpheus, and was divided into eight departments called after as many towns. Of these Salmone, Heraclea, Cicysion, Dyspontium, and Harpina are known,—the last being the reputed burial-place of Marmax, the deliverer of Hippodamia. From the time of the early investigators it has been disputed whether Pisa, which gave its name to the district, has ever been a city, or was only a fountain or a hill. By far the most important spot in Pisatis was the scene of the great Olympic games, on the northern bank of the Alpheus; but for details in regard to the locality, and the results of the explorations commenced in 1875, the reader must be referred to the special article OLYMPIA. Triphylia stretches south from the Alpheus to the Neda, which forms the boundary towards Messenia. Of the nine towns mentioned by Polybius, only two attained to any considerable influence—Lepreus and Macistus, which gave the names of Lepreatis and Macistia to the southern and northern halves of Triphylia. The former was the seat of a strongly independent population, and continued to take every opportunity of resisting the supremacy of the Eleans. In the time of Pausanias it was in a very decadent condition, and possessed only a poor brick-built temple of Demeter; but considerable remains of its outer walls are still in existence near the village of Strovitzi, on a part of the Minthe range.

The original inhabitants of Elis were called Caucones and Paroreatæ. From traces of the worship of Venus in the city of Elis, and from the presence of such names as Same and Iardanus, it is believed that the Phœnicians had settlements in the country at a very remote period. The inhabitants of Elis first appear in Grecian history under the title of Epeans, as setting out for the Trojan war, and they are described by Homer as living in a state of constant hostility with their neighbors the Pylians. At the close of the eleventh century B.C., the Dorians invaded the Peloponnesus, and Elis fell to the share of Oxylus and the Ætolians. These people, amalgamating with the Epeans, formed a powerful kingdom in the north of Elis. After this many changes took place in the political distribution of the country, till at length it came to acknowledge only three tribes, each independent of the others. These tribes were the Epeans, Minyæ, and Eleans. Before the end of the eighth century B.C., however, the Eleans had vanquished both their rivals, and established their supremacy over the whole country. Among the other advantages which they thus gained was the right of celebrating the Olympic games, which had formerly been the prerogative of the Pisans. The attempts which this people made to recover their lost privilege, during a period of nearly two hundred years, ended at length in the total destruction of their city by the Eleans. From the time of this event (572 B.C.) till the Peloponnesian war, the peace of Elis remained undisturbed. In that great contest Elis sided at first with

Sparta; but that power, jealous of the increasing prosperity of its ally, availed itself of the first pretext to pick a quarrel. At the battle of Mantinea the Eleans fought against the Spartans, who, as soon as the war came to a close, took vengeance upon them by depriving them of Triphylia and the towns of the Acrorea. The Eleans made no attempt to re-establish their authority over these places, till the star of Thebes rose in the ascendant after the battle of Leuctra. It is not unlikely that they would have effected their purpose had not the Arcadian confederacy come to the assistance of the Triphylians. In 366 B.C. hostilities broke out between them, and though the Eleans were at first successful, they were soon overpowered, and their capital very nearly fell into the hands of the enemy. Unable to make head against their opponents, they applied for assistance to the Spartans, who invaded Arcadia, and forced the Arcadians to recall their troops from Elis. The general result of this war was the restoration of their territory to the Eleans, who were also again invested with the right of holding the Olympic games. During the Macedonian supremacy in Greece they sided with the victors, but refused to fight against their countrymen. After the death of Alexander they renounced the Macedonian alliance. At a subsequent period they joined the Ætolian League, but persistently refused to identify themselves with the Achæans. When the whole of Greece fell under the Roman yoke, the sanctity of Olympia secured for the Eleans a certain amount of indulgence. The games still continued to attract to the country large numbers of strangers, until they were finally put down by Theodosius in 394, two years previous to the utter destruction of the country by the Gothic invasion under Alaric. In later times Elis fell successively into the hands of the Franks and the Venetians, under whose rule it recovered to some extent its ancient prosperity. By the latter people the province of Belvedere on the Peneus was called, in consequence of its fertility, "the milch cow of the Morea."

ELIS, the chief city in the above country, was situated on the river Peneus, just where it passes from the mountainous district of Acrorea into the champaign below. According to native tradition, it was originally founded by Oxylus, the leader of the Ætolians, whose statue stood in the market-place. In 471 B.C. it received a great extension by the incorporation, or "synoikismos," of various small hamlets, whose inhabitants took up their abode in the city. Up to this date it only occupied the ridge of the hill now called Kalascopi, to the south of the Peneus, but afterwards it spread out in several suburbs, and even to the other side of the stream. As all the athletes who intended to take part in the Olympic games were obliged to undergo a month's training in the city, its gymnasiums were among its principal institutions. They were three in number—the "Xystos," with its pillared galleries, its avenues of plane trees, its plethrion or wrestling-place, its altars to Hercules, to Eros and Anteros, to Demeter and Cora, and its cenotaph of Achilles; the "Tetragonon," appropriated to the lighter exercises, and adorned with a statue of Zeus; and the "Maltho," in the interior of which was a hall or council chamber called Lalichmion after its founder. Among the other objects of interest were the temple of Artemis Philomirax; the Hellanodicæum, or office of the Hellanodicasts; the Corcyrean Hall, a building in the Dorian style with two façades, built of spoils from Corcyra; a temple of Apollo Acesius; a temple of Silenus; an ancient structure supported on oaken pillars and reputed to be the burial-place of Oxylus; the building where the sixteen women of Elis were wont to weave a robe for the statue of Hera at Olympia; and the shrine of Dionysus, whose festival, the Thyia, was yearly celebrated in the neighborhood. The history of the town is closely identified with that of the country. In 399 B.C. it was occupied by Agis, king of Sparta. The acropolis was fortified in 312 by Telesphorus, the admiral of Antigonus, but it was shortly afterwards dismantled by Philemon, another of his generals. A view of the site is given by Stanhope.

See J. Spencer Stanhope, *Olympia and Elis*, 1824, folio; Leake, *Morea*, 1830; Curtius, *Peloponnesus*, 1851–2; Schiller, *Stämme und Staaten Griechenlands;* Bursian, *Geographie von Griechenland*, 1868–72.

ELISHA (literally, *God is deliverance;* LXX., 'Ελισαιέ; N. T., *Eliseus*), the disciple and successor of Elijah, was the son of Shaphat of Abel-meholah, which lay in the valley of the Jordan. He was called to the prophetic office in the manner already related (see ELIJAH), some time before the death of Ahab, and he survived until the reign of Joash. His official career thus appears to have extended over a period of nearly sixty years. The relation between Elijah and Elisha was of a particularly close kind, and may be compared with that between Moses and Joshua or David and Solomon. The one is the complement of the other; the resemblances, and still more the marked contrast between the character and activity of each, qualified both together for the common discharge of one great work by "diversity of operation." The difference between them is much more striking than the resemblance. Elijah is the prophet of the wilderness, rugged and austere; Elisha is the prophet of civilized life, of the city and the court, with the dress, manners, and appearance of "other grave citizens." Elijah is the messenger of vengeance, sudden, fierce, and overwhelming; Elisha is the messenger of mercy and restoration. Elijah's miracles, with few exceptions, are works of wrath and destruction; Elisha's miracles, with but one notable exception, are works of beneficence and healing. Elijah is the "prophet as fire" (Ecclesiasticus xlviii. 1), an abnormal agent working for exceptional ends; Elisha is the "holy man of God which passeth by us continually," mixing in the common life of the people, and promoting the advancement of the kingdom of God in its ordinary channels of mercy, righteousness and peace.

Though the duration of Elisha's career, with the approximate dates of its beginning and end, can be fixed, it is impossible to settle a detailed chronology of his life. In most of the events narrated no further indication of time is given than by the words "the king of Israel," the name not being specified, so that it is impossible to tell which king is meant. There are two instances at least in which the order of time is obviously the reverse of the order of narrative (compare 2 Kings viii. 1–6 with 2 Kings v. 27, and 2 Kings xiii. 14–21 with 2 Kings xiii. 13). There are besides this other grounds, which it would be out of place to state here, for concluding that the narrative as we now have it has been disarranged and is incomplete. The fact, however, of dislocation and probable mutilation of the original documents requires to be borne in mind in dealing with the life of Elisha. It may serve not only to explain the insuperable difficulties of a detailed chronology, but also to throw some light on the altogether exceptional character of the miraculous element in Elisha's history. Not only are the miracles very numerous, even more so than in the case of Elijah, but, as has been frequently pointed out, they stand in a different relation to the man and his work from that in which the miracles of Elijah or any of the wonder-working prophets do. With all the other prophets the primary function is spiritual teaching,—miracles, even though numerous and many of them symbolical like Elisha's, are only accessory. With Elisha, on the other hand, miracles seem the principal function, and the spiritual teaching is altogether subsidiary.

An obvious though only very partial explanation of the superabundance of miracles in Elisha's life is suggested by the fact that several of them were merely repetitions or doubles of those of his master and predecessor. Such were his first miracle, when returning across the Jordan he made a dry path for himself in the same manner as Elijah (2 Kings ii. 14); the increase of the widow's pot of oil (2 Kings iv. 1–7); and the restoration of the son of the woman of Shunem to life (2 Kings iv. 18–37). It is to be observed, however, that with all the similarity there is a very considerable difference in the circumstances in the two cases, which makes it difficult to accept the theory that stories from the earlier life have been imported by mistake into the later. Besides, this theory, even if tenable, applies only to three of the miracles, and leaves unexplained a much larger number which are not only not repetitions of those of Elijah, but, as has already been pointed out, have an entirely opposite character. The healing of the water of Jericho by putting salt in it (2 Kings ii. 19–21), the provision of water for the army of Jehoshaphat in the arid desert (2 Kings iii. 6–20), the neutralizing by meal of the poison in the pottage of the famine-stricken sons of the prophets at Jericho (2 Kings iv. 38–41), the healing of Naaman the Syrian (2 Kings v. 1–19), and the causing the iron axehead that had sunk in the water to rise to the surface (2 Kings vi. 1–7), are all instances of the beneficence which was the general characteristic of Elisha's wonder-working activity in contrast to that of Elijah. Another miracle of the same class, the feeding of a hundred men with twenty loaves so that something was left over (2 Kings iv. 42–44), deserves mention by itself as the most striking, though not the only instance of a resemblance between the work of

Elisha and that of Jesus, to which commentators have frequently drawn attention. The one distinct exception to the general beneficence of Elisha's activity—the destruction of the forty-two children who mocked him as he was going up to Bethel (2 Kings ii. 23–25)—presents an ethical difficulty which is scarcely satisfactorily removed by the suggestion that the narrative has lost some particulars which would have shown the real enormity of the offence of the children. The leprosy brought upon Gehazi (2 Kings v. 20–27), though a miracle of judgment, scarcely belongs to the same class as the other. The wonder-working power of Elisha is represented as continuing even after his death. As the feeding of the hundred men and the cure of leprosy connect his work with that of Jesus, so the quickening of the dead man who was cast into his sepulchre by the mere contact with his bones (2 Kings xiii. 21) is the most striking instance of an analogy between his miracles and those recorded of mediæval saints. Stanley in reference to this has remarked that in the life of Elisha, "alone in the sacred history, the gulf between biblical and ecclesiastical miracles almost disappears."

The place which Elisha filled in the history of Israel during his long career as a prophet was, apart altogether from his wonder-working, one of great influence and importance. In the natural as in the supernatural sphere of his activity the most noteworthy thing is the contrast between him and his predecessor. Elijah interfered in the history of his country as the prophet of exclusiveness, Elisha as the prophet of comprehension. During the reign of Jehoram he acted at several important crises as the king's divine counsellor and guide. At the first of these, when he delivered the army that had been brought out against Moab from a threatened dearth of water (2 Kings iii.), he plainly intimates that, but for his regard to Jehoshaphat, the king of Judah, who was in alliance with Israel, he would not have interfered. His next signal interference was during the incursions of the Syrians, when he disclosed the plans of the invaders to Jehoram with such effect that they were again and again ("not once nor twice") baffled (2 Kings vi. 8–23). When Benhadad, the king of Syria, is informed that "Elisha, the prophet that is in Israel, telleth the king of Israel the words that thou speakest in thy bed-chamber," he at once sends an army to Dothan, where the prophet is residing, in order to take captive the destroyer of his plans. At the prayer of Elisha an army of horses and chariots of fire is revealed to his servant surrounding the prophet. At a second prayer the invaders are struck blind, and in this state they are led by Elisha to Samaria, where their sight is restored. Their lives are spared at the command of the prophet, and they return home so impressed with the supernatural power that is opposed to them that their incursions thenceforward cease. The marauding incursions were given up, however, only to be followed by the invasion of a regular army under Benhadad, which laid siege to Samaria, and so caused a famine of the severest kind (2 Kings vi. 24–29). The calamity was imputed by Jehoram to the influence of Elisha, and he ordered the prophet to be immediately put to death. Forewarned of the danger, Elisha ordered the messenger who had been sent to slay him to be detained at the door, and when immediately afterwards the king himself came ("messenger" in 2 Kings vi. 33 should rather be *king*), predicted a great plenty within twenty-four hours. The apparently incredible prophecy was fulfilled by the flight of the Syrian army under the circumstances stated in 2 Kings vii. After the episode with regard to the woman of Shunem (2 Kings viii. 1–6), which, as has been already pointed out, is introduced out of its chronological order, Elisha is represented as at Damascus (2 Kings viii. 7–15). The object for which he went to the Syrian capital is not expressly stated, but it evidently was to fulfil the second command laid upon Elijah, viz., to anoint Hazael as king of Syria. The reverence with which the heathen monarch Benhadad addressed Elisha deserves to be noted as showing the extent of the prophet's influence. In sending to know the issue of his illness, the king causes himself to be styled "*Thy son* Benhadad." Equally remarkable is the very ambiguous nature of Elisha's reply (2 Kings viii. 10), which may, however, be due to the doubtful state of the Hebrew text. The next, and, as it proved, the last important interference of Elisha in the history of his country, constituted the fulfilment of the third of the commands laid upon Elijah. The work of anointing Jehu to be king over Israel was performed by deputy, as related in 2 Kings ix. 1–3. During the reigns of Jehu and Jehoahaz the Scripture narrative contains no notice of Elisha, but from the circumstances of his death (2 Kings xiii. 14–21) it is clear that he had continued to hold the office and receive the honors of a prophet. Joash the king waited on him on his death-bed, and addressed him in the same words of profound reverence and regret which he himself had used to Elijah: "O my father, my father, the chariot of Israel and the horsemen thereof." By the result of a symbolic discharge of arrows he informed the king of his coming success against Syria, and immediately thereafter he died. It seems fitly to complete the contrast between him and his greater predecessor to be told expressly that "he was buried." The miracle wrought at his tomb has been already noticed.

Elisha is canonized in the Greek Church, his festival being on the 14th June, under which date his life is entered in the *Acta Sanctorum*.

ELIZABETH, queen of England, one of the most fortunate and illustrious of modern sovereigns, was born in the palace of Greenwich on the 7th of September, 1533. She was the only surviving issue of the ill-starred union between Henry VIII. and Anne Boleyn, which extended over a space of less than three years. Anne was crowned at Westminster June 15, 1533, and was beheaded within the Tower of London May 19, 1536. The girlish beauty and vivacity of Anne Boleyn, with her brief career of royal splendor and her violent death, invest her story with a portion of romantic interest; but she does not seem to have possessed any solid virtues or intellectual superiority. The name of Elizabeth cannot be added to the list of eminent persons who are said to have inherited their peculiar talents and dispositions from the side of the mother. On the contrary, she closely resembled her father in many respects,—in his stout heart and haughty temper, his strong self-will and energy, and his love of courtly pomp and magnificence. Combined with these, however, there was in Elizabeth a degree of politic caution and wisdom, with no small dissimulation and artifice, which certainly does not appear in the character of "bluff King Harry." Early hardships and dangers had taught Elizabeth prudence and suspicion, as well as afforded opportunity in her forced retirement for the pursuit of learning and for private accomplishments. The period of her youth was an interesting and memorable one in English history. The doctrines of the Reformation had spread from Germany to this country; and the passions and interests of Henry led him to adopt in part the new faith, or at least to abjure the grand tenet of the Papal supremacy. Anne Boleyn, by her charms and influence, facilitated this great change; and there is historical truth as well as poetical beauty in the couplet of Gray,

> "That Love could teach a monarch to be wise,
> And gospel light first dawn'd from Boleyn's eyes."

The Protestantism of England was henceforth linked to Elizabeth's title to the crown. She was in her fourteenth year when her father King Henry died. Her education had been carefully attended to, latterly under the superintendence of good Catherine Parr, the last of Henry's queens. The young princess was instructed in Greek and Latin, first by William Grindal, and afterwards by Roger Ascham, who has described his pupil in glowing terms as "exempt from female weakness," and endued with a masculine power of application, quick apprehension, and retentive memory. She spoke French and Italian with fluency, was elegant in her penmanship, whether in the Greek or Roman character, and was skilful in music, though she did not delight in it. "With respect to personal decoration," adds Ascham, "she greatly prefers a simple elegance to show and splendor." This last characteristic, if it ever existed, did not abide with Elizabeth. Her love of rich dresses, jewels, and other ornaments was excessive; and at her death she is said to have had about 2000 costly suits of all countries in her wardrobe. Nor can it be said that even at the tender age of sixteen, when Roger Ascham drew her flattering portrait, Elizabeth was exempt from female weakness. After the death of Henry, the queen-dowager married the Lord Admiral Seymour, whose gallantries and ambition embittered her latter days. Seymour paid court to the Princess Elizabeth, and with the connivance of her governess, Mrs. Ashley, obtained frequent interviews, in which much boisterous and indelicate familiarity passed. The graver court ladies found fault with "my lady Elizabeth's going in a night in a barge upon Thames, and for other light parts;" and the scandal proceeded so far as to become matter of examination by the council. Mrs. Ashley and Thomas Parry, cofferer of the princess's household (afterwards patronized by Elizabeth), were committed for a time to the Tower, and Elizabeth underwent an examination by Sir Thomas Tyrwhit, but would confess nothing. "She hath a very good wit," said Tyrwhit, "and nothing is gotten of her but by great policy." The subsequent disgrace and death of Seymour closed this first of Elizabeth's love-passages; she applied herself diligently to her studies under Ascham, and maintained that "policy" and caution which events rendered more than ever necessary.

The premature death of Edward VI. called forth a display of Elizabeth's sagacity and courage. Edward had been prevailed upon by the duke of Northumberland to dispose of the crown by will to his cousin Lady Jane Grey. The two sisters, Mary and Elizabeth, on whom the succession had been settled by the testamentary provisions of Henry VIII., as well as by statute, were thus excluded. Mary's friends immediately took up arms; Elizabeth was asked to resign her title in consideration of a sum of money, and certain lands which should be assigned to her; but she rejected the proposal, adding that her elder sister should be treated with first, as during Mary's lifetime she herself had no right to the throne. Elizabeth then rallied her friends and followers, and when Mary approached London, successful and triumphant, she was met by Elizabeth at the head 1000 horse—knights, squires, and ladies, with their attendants. Such a congratulation merited a different acknowledgment from that which Elizabeth was fated to experience. But the temper of Mary, never frank or amiable, had been soured by neglect, persecution, and ill-health; and her fanatical devotion to the ancient religion had become the absorbing and ruling passion of her mind. She was not devoid of private virtues,—certainly excelling Elizabeth in sincerity and depth of feeling; but her virtues "walked a narrow round;" and whenever the Romish Church was in question, all feelings of private tenderness, and all considerations of public expediency or justice, were with Mary as flax in the fire. The five years of her reign are perhaps the most un-English epoch in our annals.[1]

To escape from indignities and persecution at court, Elizabeth was suffered to retire, though carefully watched, to her house of Ashridge, in Buckinghamshire. Wyat's insurrection, prompted by the rumored marriage of Mary with Philip of Spain, made her still more an object of suspicion and distrust, as the hopes of the Protestant party were on all occasions turned to Elizabeth. The young princess was taken from Ashridge and privately committed to the Tower. Her death was demanded by some of the bigoted adherents of the court, but Mary dared not and probably did not desire to proceed to this extremity; Philip, when allied to the English crown, interceded on behalf of the fair captive, and Elizabeth was removed to Woodstock, under care of a fierce Catholic, Sir Henry Bedingfield. Her extreme wariness and circumspection baffled every effort to entrap her. She conformed outwardly to the Catholic Church, opening a chapel in her house at Woodstock, and keeping a large crucifix in her chamber. This conformity was not unnaturally ascribed to dissimulation, but part was probably real. To the end of her life, Elizabeth retained a portion of the old belief. She had always a crucifix with lighted tapers before it in her private chapel; she put up prayers to the Virgin (being, she said, a virgin herself, she saw no sin in this); she disliked all preaching and controversy on the subject of the real presence; and she was zealous almost to slaying against the marriage of the clergy. She was anxious to retain as much as possible of the Catholic ceremonial and the splendid celebrations of the church festivals, which the ardent reformers would gladly have swept away, as had been done in Scotland. The Anglican Church was a compromise.

The wretched and inglorious reign of Mary terminated on the 17th of November, 1558. Elizabeth heard the news of her accession at Hatfield, and she fell down on her knees, exclaiming: *A Domino factum est istud, et est mirabile oculis nostris*—"It is the Lord's doing, it is marvellous in our eyes"—words which she afterwards caused to be stamped on a gold coin, impressing on her silver coin another pious motto, *Posui Deum adjutorum meum*—"I have chosen God for my helper." All her perils were now passed. The nation received her with unbounded enthusiasm. Church bells were rung, bonfires blazed, tables were spread on the streets, the Protestants exulted with a holy joy.

Elizabeth was in her twenty-fifth year when she ascended the throne. She had been better disciplined and trained for her high trust than most princes, yet the difficulties that surrounded the English crown at this time might well have appalled her. The nation was struggling in a war with France, trade was much decayed, Calais had been lost, and England was distracted by religious divisions and animosities. All Catholic Europe might be expected to be arrayed against the Protestant queen of England. Elizabeth, however, at once chose the better part for herself and the nation. Without waiting for the assembling of her first parliament, she ordered the church service to be read in English, and the elevation of the host to be discontinued. But before this could be known abroad, she had instructed the English ambassador at Rome to notify her accession to the pope. Paul IV., then Pontiff, arrogantly replied that England was a fief of the Holy See, that Elizabeth was illegitimate, and could not inherit the crown, and that she should renounce all her pretensions and submit to his decision. If Elizabeth had ever wavered as to the course she should pursue, this papal fulmination must have fixed her determination. Twelve years afterwards, a subsequent pope, Pius V., issued a bull releasing English Catholics from their allegiance to the queen, and formally depriving her of her title to the throne. But the thunders of the Vatican, like the threats of the Escorial, fell harmless on the English shores. The nation, under its Protestant monarch and her wise counsellors, the Lord-keeper Bacon, Cecil (afterwards Lord Burghley), Walsingham, Throckmorton, Sir Ralph Sadler, and others, pursued its triumphant course, while its naval strength and glory were augmented beyond all former precedent. The exploits of the gallant sea-rovers Drake, Hawkins, and Frobisher, the heroic deaths of the brave admirals Gilbert and Grenville, and the transatlantic adventures of Raleigh—are still unsurpassed in romantic interest. The government of Elizabeth and the public events of her reign will fall to be recorded in another part of this work, under the head of ENGLAND. Her first parliament passed the famous Acts of Supremacy and Uniformity, which struck directly at the papal power. All clergymen and public functionaries were obliged to renounce the temporal and spiritual jurisdiction of every foreign prince and prelate; and all ministers, whether beneficed or not, were prohibited from using any but the established liturgy. These statutes were carried out with considerable severity; many Catholics suffered death; but all might have saved themselves, if they had explicitly denied the right of the pope to depose the queen. The Puritans and nonconformists, on the other hand, were content to bear some portion of the burden of intolerence and oppression, from the consideration that Elizabeth was the bulwark of Protestantism. If they lost her firm hand they lost all; and the numerous plots and machinations of the Catholics against the queen's life showed how highly it was valued, and how precious it was to Protestant Europe. In the latter part of the queen's reign, her domestic and fiscal regulations were justly open to censure. The abuse of monopolies had grown to be a great evil; grants of exclusive right to deal in almost all commodities had been given to the royal favorites, who were exorbitant in their demands, and oppressed the people at pleasure. Elizabeth wisely yielded to the growing strength of the Commons, and the monopolies complained of were cancelled. The monarchy, though as yet arbitrary and in some respects undefined, was still, in essential points, limited by law.

---

[1] Miss Lucy Aikin, in her *Memoirs of the Court of Elizabeth*, praises the magnanimity of Elizabeth in allowing Shakespeare's drama of *Henry VIII.*, in which the wrongs and sufferings of Catherine of Aragon are embalmed, to be publicly offered to the compassion of her people. We wish that this instance of magnanimity could be justly ascribed to the queen; but it seems certain that Shakespeare's *Henry VIII.* was not produced till after Elizabeth's death. No poet would have dared to hint at the death of the queen while she lived; and Cranmer's prophecy in the fifth act speaks of the death of Elizabeth and of her successor James. We have Ben Jonson's testimony as to Shakespeare's favor with Elizabeth,—

> ——— "Those flights upon the banks of Thames,
> That so did take Eliza and our James."

And the tradition that the poet wrote his *Merry Wives of Windsor* by request of the queen, *who wished to see Falstaff in love*, is at least highly probable. One of the latest Shakespearean discoveries is that the poet, along with his "fellows" Kempe and Burbage, acted in two plays before the queen at Greenwich in December, 1594, for which they received, upon the Council's warrant, £13, 6s. 8d. and, "by way of her Majesty's favour," £6, 13s. 4d.—in all £20 (Halliwell's *Illustrations*, 1874).

One great object of the Protestants was to secure a successor to the throne by the marriage of Elizabeth. The nearest heir was Mary Queen of Scots, a zealous Catholic, who was supported by all the Catholic states, and had ostentatiously quartered the royal arms of England with her own, thus deeply offending the proud and jealous Elizabeth. The hand of the English queen was eagerly solicited by numerous suitors—by Philip of Spain, who was ambitious of continuing his connection with England, by the Archduke Charles of Austria, by Eric king of Sweden, the duke of Anjou, and others. With some of these Elizabeth negotiated and coquetted for years; to Anjou she seems to have been attached; but her affections were more deeply touched, as Mr. Hallam has remarked, by her favorite Dudley, earl of Leicester. Her early resolution, and that which ultimately prevailed over her weakness or vanity, was, that she should remain single and hold undivided power. To a deputation from the Commons on this delicate subject, she emphatically said she had resolved to live and die a virgin queen: "and for me it shall be sufficient that a marble stone declare that a queen, having reigned such a time, lived and died a virgin." She appears often to have wavered in her resolution, and, in her partiality for handsome courtiers and admirers, to have forgotten her prudence and dignity. Her partiality for Essex was undisguised—it was unhappy for both; and making Hatton chancellor because he could dance gracefully was a bold but not unsuccessful achievement. Elizabeth's fits of rage were as violent as her fits of love. Her maids of honor sometimes felt the weight of the royal hand; and when Essex once turned his back on her, she appropriately dealt him a box on the ear. As a pendant to these *nugæ*, we may add that Elizabeth swore strongly, decided and masculine oaths.

The feminine weakness and egregious vanity of Elizabeth, in the midst of so many masculine qualities of temperament and intellect, have afforded abundant matter for garrulous chroniclers. Five years after she ascended the throne, she issued a proclamation against portrait painters and engravers, who had erred in expressing "that natural representation of her majesty's person, favor, or grace," that was desired by her loving subjects, and who were ordered to desist until some "special cunning painter" might be permitted to have access to the royal presence. The works of the unskilful and common painters were, as Raleigh relates, by the queen's commandment, "knocked in pieces and cast into the fire." A long account is given by the Scottish ambassador Melville of certain interviews he had with Elizabeth when in her most gracious and pleasant mood. She showed him "my lord's picture,"—a portrait of the unworthy favorite Dudley; she changed her dress every day, "one day the English weed, another the French, and another the Italian, and so forth," asking Melville which became her best; her hair, he says, was rather reddish than yellow, and curled naturally; she inquired whether the queen of Scotland or herself was of highest stature, and Melville answering that Mary was tallest, "then," saith she, "she is too high, for I myself am neither too high nor too low." Melville praised Mary's accomplishments as a musician and dancer, and Elizabeth contrived, as if by accident, that he should hear her play upon the virginals: "she inquired whether my queen or she played best; in that I found myself obliged to give her the praise." In the matter of the dancing, Melville was also able to answer, that Mary did not dance "*so high and disposedly*" as Elizabeth. Determined to show all her accomplishments, Elizabeth addressed the wary ambassador in Italian, which she spoke "reasonably well," and in German, which, he says, was "not so good." These glimpses of the *woman* Elizabeth contrast strangely with the *sovereign*, who, at Tilbury camp, rode from rank to rank of her army, bareheaded, with a general's truncheon in her hand, declaring to her soldiers that she was resolved to live and die amongst them in the midst and heat of the battle; and that she thought it "foul scorn that Parma or Spain, or any prince of Europe, should dare to invade the borders of her realms." Language and sentiments like these, reflecting the feeling of the nation, must have insured the destruction of the troops of Parma or Spain, even if the vaunted Armada had not been sunk by the English fire or scattered by tempests. At this great crisis, however, Elizabeth owed much of her popularity and security to the wisdom of her ministers and the spirit of her people, rather than to her own patriotism and sense of duty. She had from unwise parsimony impoverished the navy, as she had previously neglected the army, and left the country comparatively defenceless. It was only after repeated applications and entreaties that Burghley and Walsingham obtained the royal consent to carry out the necessary preparations. Walsingham made large personal advances, which were never repaid. Irresolution would seem *a priori* to be a weakness alien to the despotic character of Elizabeth, yet it is certain that she was often, on momentous occasions, hesitating, wavering, and undecided. The sagacity and devotedness of her chief counsellors, though not incited or fed by the royal bounty, were her safety and her strength.

The darkest stain on the memory of Elizabeth is her treatment of Mary Queen of Scots. To have cut off Mary from the crown, settling it on her son, would have secured the Protestant succession, and Mary liberated would most probably have repaired to France, whence her revenue was derived, or to Spain. Thus the conspiracies for her release and her own machinations would have been averted. Her execution, though clamored for by the English nation, was an act of cruelty peculiarly revolting on the part of a female sovereign and kinswoman. And Elizabeth's affected reluctance to sign the death warrant, her prompting to Secretary Davison that Sir Amias Paulet should be instigated to make away with the captive queen (which the "dainty precise fellow," as Elizabeth termed him, refused to do), and her feigned grief and indignation after the event had taken place—throwing the blame on her ministers and on the unfortunate secretary who placed the warrant before her for signature—all this over-acted and disgusting hypocrisy is almost as injurious to the reputation of Elizabeth as the deed itself.

Mr. Froude has said that no trace can be found of personal animosity on the part of Elizabeth towards Mary. It is evident, however, that jealousy if not hatred animated the English queen towards her rival. The youth and beauty of Mary were a source of aversion; Elizabeth never forgave her for quartering the royal arms of England; and there was a certain malicious letter, written by Mary to Elizabeth when the captive queen was under the guardianship of the earl of Shrewsbury, that must have chafed the Tudor blood in no ordinary degree. In this epistle Mary reported some alleged speeches of the countess of Shrewsbury charging Elizabeth with licentious amours, physical defects, absurd vanity, folly, and avarice (Hume, chap. xliii.). The original letter in Mary's handwriting was seen by Prince Labanoff (*circa* 1840) among the Cecil papers in Hatfield House, where, we believe, it still remains. It is such an epistle as no woman—royalty apart—would ever forget or forgive, but there is a probability that Burghley or Walsingham may have intercepted the letter, and not ventured to deliver it to their royal mistress.

To the end of her life Elizabeth affected all the airs of a coy beauty and coquette. Even her statesmen addressed her in a strain of fulsome adulation and semi-gallantry. She was the Gloriana of Spenser, the "fair vestal throned in the west" of Shakespeare, and the idol of all the lesser poets, as well as courtiers and politicians. When Raleigh was confined in the Tower, he wrote to Cecil—trusting, no doubt, that his letter would be shown to Elizabeth—that he was in the utmost depth of misery because he could no longer see the queen. "I, that was wont to behold her riding like Alexander, hunting like Diana, walking like Venus, the gentle wind blowing her fair hair about her pure cheeks like a nymph [Elizabeth was then in her fifty-ninth year]; sometime singing like an angel, sometime playing like Orpheus," etc. Elizabeth continued her gorgeous finery and rigorous state ceremonial, and was waited upon by applauding crowds whenever she went abroad. We have a graphic picture of her in her sixty-fifth year by a German, Paul Hentzner, who saw the queen on a Sunday as she proceeded to chapel. She appeared stately and majestic; her face oblong, fair but wrinkled; her eyes small, yet black and pleasant; her nose a little hooked, her lips narrow, her teeth black, her hands slender and her fingers long (there was a special beauty in her delicate white hands, and in her audiences she took care not to hide them). She had pearls with rich drops in her ears, wore false red hair, had a small crown on her head, her bosom uncovered, her dress white silk, bordered with pearls of the size of beans, a collar of gold and jewels; and thus arrayed, Elizabeth passed along smiling graciously on the spectators, who fell down on their knees as she approached; while a marchioness bore up her train, a bevy of ladies followed her dressed in white, and she was guarded on each side by fifty gentlemen pensioners carrying gilt battle-axes.

A few years afterwards we see the eclipse of all this splendor and servility. Towards the end of March, 1603, Elizabeth was seized with her mortal illness. She became restless and melancholy, refused medicine, and sat for days and nights on cushions, silent, her finger pressed on her mouth. When asked by Cecil who should succeed her on the throne, she characteristically answered, "My seat has been the seat of kings; I will have no *rascal* to succeed me." She afterwards, when speechless, joined her hands together above her head, "in manner of a crown," to signify, in answer to another interrogatory from Cecil, that she wished the king of Scots to be her successor. She expired on the 24th of March, 1603. And thus calmly passed away the last of the Tudors, the lion-hearted Elizabeth. She was in the seventieth year of her age and forty-fifth of her reign—a period of brilliant prosperity and advancement, during which England had put forth her brightest genius, valor, and enterprise, and attained to the highest distinction and glory among the states of Europe. The "golden days of good Queen Bess" were long remembered in contrast to those of her pusillanimous successor, and this traditional splendor, in spite of historical research and juster views of government, has scarcely yet "faded into the common light of day."

Horace Walpole has assigned to Elizabeth a place in his *Catalogue of Royal and Noble Authors*, and a list of thirteen productions, exclusive of letters and speeches, is attached to the queen's name. They consist chiefly of translations from the Greek, Latin, and French, with a sonnet printed during her own lifetime, and some prayers and meditations. The learning of Elizabeth is undoubted: it was considerable even in that age of learned ladies; but her style is stiff, involved, quaint, and full of conceits—the whole evincing rather a predilection for literary and scholastic studies than literary taste or power. (R. CA.)

ELIZABETH, St. (1207–1231), of Hungary, daughter of Andrew II., king of Hungary, was born in Presburg in 1207. At four years of age she was betrothed to Louis IV., landgrave of Thuringia, and conducted to the Thuringian court to be educated under the direction of his parents. From her earliest years she is said to have evinced an aversion to worldly pleasures, and, making the early Christians her chief model, to have devoted her whole time to religion and to works of charity. She was married at the age of fourteen, and acquired such influence over her husband that he adopted her doctrines and zealously assisted her in all her charitable endeavors. On the death of Louis in 1227, Elizabeth was deprived of the regency by his brother Henry Raspe, on the pretext that she was wasting the estates by her alms; and with her three infant children she was driven from her home without being allowed to carry with her even the barest necessaries of life. She lived for some time in great hardship, but ultimately her uncle, the bishop of Bamberg, offered her an asylum in a house adjoining his palace. Through the intercession of some of the principal barons, the regency was again offered her, and her son Hermann was declared heir to the throne; but renouncing all power, and making use of her wealth only for charitable purposes, she preferred to live in seclusion at Marburg under the direction of her confessor Conrad. There she spent the remainder of her days in penances of unusual severity, and in ministrations to the sick, especially those afflicted with the most loathsome diseases. She died at Marburg, 19th November, 1231, and four years afterwards was canonized by Gregory IX. on account of the frequent miracles reported to have been performed at her tomb.

A life of Elizabeth was written by Theodore of Thuringia; and *L'Histoire de Sainte Élisabeth de Hongrie*, by Montalembert, was published at Paris in 1836. Her life has also supplied the materials for a dramatic poem by Charles Kingsley, entitled the *Saint's Tragedy*.

ELIZABETH PETROVNA (1709–1762), empress of Russia, daughter of Peter the Great and of Catherine I., was born on the 5th September, 1709. In consequence of a law of her father, by which the sovereign had the power to choose his successor, she had no legal claim to the throne. The empress Anna Ivanova died in 1740. She had appointed Ivan, son of her niece Anne duchess of Brunswick, a child only a few months old, to the throne, with Biron, her favorite, regent. Elizabeth was quite contented with this arrangement. She declared that love was the supreme good, and that she had no desire for the cares and honors of a crown. But the prestige of her father's name, and the favor in which she stood with the Russian people, rendered her an object of jealousy to the regent and to the mother of the presumptive heir; and on her refusing a proposal of marriage with the duke of Brunswick, brother-in-law of Anne, it was hinted to her that she should take the veil. She might not even then have listened to the suggestions of those who counselled a conspiracy, had she not been persuaded by Lestocq, her physician and favorite, that the suspicions of the Government were so much aroused that to go back or to delay was no longer compatible with safety. Yielding to those representations, she resolved to make the venture, and on the 6th December, 1741, entered the barracks of the Preobrajensky guards and endeavored to induce them to swear allegiance to her. Notwithstanding her powerful appeal and the promise of high rewards, all hesitated with the exception of a single company—old soldiers of Peter the Great; but placing herself at the head of this small band, she entered the imperial palace and made prisoners of the regent and of Anne and her son. She possessed already the affections of the people, and at once her authority was firmly established. Her administration was successful both at home and abroad. Although she was ruled by worthless favorites, who followed each other in rapid succession, her reign was very popular with the people, who surnamed her the Clement. She was indolent and sensual, but she possessed considerable abilities, and an energetic will when it was roused to exertion. She had some taste for literature and the fine arts, and founded the university of Moscow, and the Academy for the Fine Arts of St. Petersburg. In 1743 she brought the war with Sweden to a close by an advantageous treaty. She successfully assisted Maria Theresa against Frederick the Great, and in this way contributed to the peace of Aix-la-Chapelle in 1748. After this, irritated, it is said, by a reported witty remark of Frederick, she took part in the Seven Years' War, and by successive victories reduced that monarch to great straits, from which he was only delivered by her death (Jan. 5, 1762).

ELIZABETH, originally Elizabethtown, a city of the United States, capital of Union county, New Jersey, is situated eleven miles W.S.W. of New York, on the Elizabeth river, near its junction with Staten Sound. It is a well-built and flourishing place, and possesses twenty-five churches, a Roman Catholic nunnery, a court-house and county-jail, a city hall, two high schools, a business college, a collegiate school, an almshouse, and an orphan asylum. Besides a great establishment for the manufacture of the "Singer" sewing machine, there are breweries, foundries, potteries, and factories for edge-tools, saws, stoves, carriages, oil-cloth, etc. The port, which is open to vessels of 300 tons, is one of the greatest coal-shipping dépôts in the United States, forming, as it does, an outlet for the Pennsylvanian fields. The town dates from 1665; it was the capital of New Jersey from February, 1755, to September, 1790, and obtained its city charter in 1865. Population in 1850, 5583; in 1870, 20,832.

ELIZABETHGRAD, or Yelizavetgrad, a fortified town and military dépôt of South Russia, in the government of Kherson, is situated on the left bank of the Ingul, 153 miles N. by W. of Kherson, in 48° 31′ N. lat. and 31° 17′ E. long. It is built with great regularity, and its streets are spacious and in some cases lined with trees. It has a citadel with six bastions, a hospital, and several churches. Its trade is considerable, and its annual autumnal fair is the one most frequented in the government. It was founded in 1754, and was named after the empress Elizabeth. The citadel was garrisoned with Cossacks, and the outskirts were settled with schismatics, or *raskolniks*, who had returned from Turkey. Including its four suburbs, the population of Elizabethgrad in 1873 was 31,962.

ELIZABETHPOL, Yelizavetpol, or Gansha, the chief town of a government in the province of Tiflis, in Russian Transcaucasia, is situated 1449 feet above the sea-level, on an affluent of the Kur, 90 miles south-east of Tiflis, in 40° 40′ 42″ N. lat. and 46° 21′ 19″ E. long. It was at one time a place of considerable importance, but on account of having been frequently stormed and pillaged is now in a somewhat dilapidated condition. The streets are narrow, and most of the houses low-roofed and without windows, but it has several elegant mosques and other public buildings. It is divided into four quarters, two of which are inhabited by Armenians and two by Tatars. The inhabitants are engaged chiefly in horticulture, agriculture, and the rearing of silkworms and cattle. Gandzak, Kanga, or Kendzhe, as the town was formerly called, first appears in history in 1088, when it was under the rule of the Turkish emir Vuzan, and was included in the Armenian province of Artza'kh. Its extent at that time is attested by the twenty-two ancient cemeteries which still exist. The present town was founded by Shah Abbas, four miles from the site of the older city, which is now marked by the Green Mosque. It continued in Mahometan possession till 1804, when it was stormed by the Russians under Prince Tsitsianoff, and received its present name in honor of Elizabeth, daughter of Alexander I. In 1826 it was the scene of a great victory over the Persians. The population in 1873 was 15,439.

ELK. See Deer, vol. vii. p. 23.

ELLENBOROUGH, Edward Law, Baron (1750–1818), chief-justice of the Court of King's Bench, was born on the 16th November, 1750, at Great Salkeld, in Cumberland, of which place his father, afterwards bishop of Carlisle, was at the time rector. Educated at the Charterhouse school and at St. Peter's College, Cambridge, he passed as third wrangler, and was soon afterwards elected to a fellowship at Trinity. In spite of his father's strong wish that he should take orders, he chose the legal profession, and on quitting the university was entered at Lincoln's Inn. After spending five years as a "special pleader under the bar," he was called to the bar in 1780. He chose the Northern Circuit, and in a very short time obtained a lucrative practice and a high reputation. In 1787 he was appointed principal counsel for Warren Hastings in the celebrated impeachment trial before the House of Lords, and the ability with which he conducted the defence was universally recognized. He had commenced his political career as a Whig, but, like many others, he saw in the French Revolution a reason for changing sides, and became a supporter of Pitt. On the formation of the Addington ministry in 1801, he was appointed attorney-general, and in the following year he succeeded Lord Kenyon as chief-justice of the King's Bench. On being raised to the bench he was created a peer, taking his title from the village of Ellenborough in Cumberland, where his maternal ancestors had long held a small patrimony. In 1806, on the formation of Lord Grenville's ministry "of all the talents," Lord Ellenborough declined the offer of the Great Seal, but accepted a seat in the Cabinet. His doing so while he retained the chief-justiceship was much criticised at the time, and, though not without precedent, is open to obvious objections on constitutional grounds. As a judge he had grave faults, though his decisions displayed profound legal knowledge, and in mercantile law especially were reckoned of high authority. He was harsh and overbearing to counsel, and in the political trials which were so frequent in his time showed an unmistakable bias against the accused. In the trial of Hone for blasphemy in 1817, Ellenborough directed the jury to find a verdict of guilty, and their acquittal of the prisoner is generally said to have hastened his death. He resigned his judicial office in November, 1818, and died on the 13th December following.

ELLENBOROUGH, Edward Law, Earl of (1790–1871), the eldest son of Baron Ellenborough, noticed above, was born in 1790, was educated at Eton and St. John's College, Cambridge, and represented the subsequently disfranchised borough of St. Michael's in the House of Commons, until the death of his father in 1818 gave him a seat in the House of Lords. He was twice married; his only child died young; his second wife was divorced by Act of Parliament in 1830. By the friendship of the duke of Wellington, which he retained all through his Indian career, Lord Ellenborough was appointed lord privy seal, and then president of the Board of Control, in the year 1828. In 1834 and in 1841 for a few weeks he again held the latter office, the duties of which at once made him familiar with the affairs of India, and gave him control over the court of directors. Sir Robert Peel appointed him governor-general with the Queen's approval. He discharged the duties of the high position from the 28th February, 1842, to the 15th June, 1844, when the directors exercised their power of recalling him. He finally left Calcutta on the 1st August, 1844. His Indian administration of two and a half years, or half the usual term of service, was from first to last a subject of hostile criticism. His own letters sent monthly to the Queen, and his correspondence with the duke of Wellington, published in 1874 after his death, enable us to form an intelligent and impartial judgment of his meteor-like career. The events in dispute are his policy towards Afghanistan and the army and captives there, his conquest of Sind, and his campaign in Gwalior. He was fortunate in having as his private secretary Captain (afterwards Sir Henry) Durand, the accomplished engineer officer and statesman, who died in 1871 when lieutenant-governor of the Punjab. Although he was absorbed in military and foreign politics, his administration was fertile in peaceful reforms, due to his colleague, Mr. Wilberforce Bird, who purged the police, put down state lotteries, and prohibited slavery, with Ellenborough's hearty support.

The impartial study of Lord Ellenborough's correspondence in the light of the records and criticisms of the times must confirm the contemporary verdict against him on the questions of Afghanistan and Sind, and may lead us to approve of his action in Gwalior. All through his brief Indian career, moreover, his severest critics must admire the splendor of his intellect (which put him in the first rank of orators in the House of Lords down almost to the year of his death), the purity of his public patronage, and the energy of his devotion to the service of his country. The same judgment which marked his later criticism of others was wanting when he held the almost irresponsible power of governor-general, to make his rule as useful as it was remarkable. If men like Durand and Wilberforce Bird helped him by the possession of the official and ethical virtues which he lacked, we must not forget that Sir Charles Napier led his Government and himself still farther to that extreme of rashness and impulse which was his bane. And against his only too apparent contempt or indifference for all things not military we must set the statesmanlike views expressed to the Queen and the duke of Wellington on the critical position of Great Britain in the East, and the necessity for strengthening it by military reforms. He repeated what the greater governor-general Wellesley had urged, but in vain, on the East India Company at the beginning of the century, and Dalhousie again in 1854–56. The penalty came in the mutiny campaigns of 1857, as it had been foreshadowed in the Cabul disasters of 1838–42.

It was to retrieve these disasters that Lord Ellenborough was sent out. If he had a difficult task, he found the tide of fortune just on the turn. In his proclamation of the 15th March, 1842, as in his memorandum for the Queen dated the 18th, he stated with characteristic clearness and eloquence the duty of first inflicting some signal and decisive blow on the Afghans, and then leaving them to govern themselves under the sovereign of their own choice. Unhappily, when he left his council for Upper India, and learned the trifling failure of General England, he instructed Pollock and Nott, who were advancing triumphantly with their avenging columns to rescue the captives, to fall back. Not a word was said of the nine ladies, twenty officers, and fourteen children who were being pursued from prison to prison in the hills, in spite of the heroic efforts of one of their number, Major-General Colin Mackenzie, who still survives, to secure their honorable release. Even such an object as "that of avenging our losses and re-establishing our military character in all its original brilliancy" was declared not now to be justifiable. How this charge was received by the "illustrious" troops of Jellalabad and the advancing conquerors of Ghuznee and Akbar Khan, the *Life of Pollock* and the journals of the day testify. The shout of indignation was too much even for Ellenborough, but he only added to it derision when he shirked responsibility by directing Pollock and Nott to retire by the roundabout way of Cabul if they could! The army proved true to the governor-general's earlier proclamation rather than to his later fears; the hostages were rescued, the scene of Sir Alexander Burnes's murder in the heart of Cabul was burned down. Dost Mahomed was quietly dismissed from a prison in Calcutta to the throne in the Bala Hissar, and Ellenborough presided over the painting of the elephants for an unprecedented military spectacle at Ferozepore, on the south bank of the Sutlej. But this was not the only piece of theatrical display which capped with ridicule the horrors and the follies of these four years in Afghanistan. When Sultan Mahmoud, in 1024, sacked the Hindu temple of Somnauth on the north-west coast of India, he carried off, with the treasures, the richly studded sandal-wood gates of the fane, and set them up in his capital of Ghuznee. The Mahometan puppet of the English, Shah Shooja, had been asked, when ruler of Afghanistan, to restore them to India; and what he had failed to do the Christian ruler of opposing Mahometans and Hindus resolved to effect in the most solemn and public manner. In vain had Major (now Sir Henry) Rawlinson proved that they were only reproductions of the original gates, to which the Ghuznee Moulvies clung merely as a source of offerings from the faithful who visited the old conqueror's tomb. In vain did the Hindu sepoys show the most chilling indifference to the belauded restoration. Ellenborough could not resist the temptation to copy Napoleon's magniloquent proclamation under the Pyramids. The desecrated or fraudulent folding doors—more "glorious trophy of successful warfare" than the heroic hostages whose names Lady Sale's *Journals*, Mackenzie's martyr-like courage, and Vincent Eyre's book have made imperishable—were conveyed on a triumphal car to the fort of Agra, and there they lie among the old muskets to this day. That Somnauth proclamation was the first step towards its author's recall, but it had the one good result of calling forth Lord Macaulay's most brilliant philippic in the House of Commons on the 9th March, 1843.

Hardly had Ellenborough issued his medal with the legend "Pax Asiæ Restituta" when he was at war with the Ameers of Sind. The tributary Ameers had on the whole been faithful, for Major (afterwards Sir James) Outram controlled them. But he had reported the opposition of a few, and Ellenborough ordered an inquiry. His instructions were admirable, in equity as well as energy, and if Outram had been left to carry them out all would have been well. But the duty was intrusted to Sir Charles Napier, with full political as well as military powers. And to add to the evil, Meer Ali Morad intrigued with both sides so effectually that he betrayed the Ameers on the one hand, while he deluded Sir Charles Napier to their destruction on the other. Ellenborough was led on till events were beyond his control, and his own just and merciful instructions were forgotten. Sir Charles Napier made more than one confession like this: "We have no right to seize Sind, yet we shall do so, and a very advantageous, useful, and humane piece of rascality it will be." The battles of Meanee and Dubba, or Hydrabad, followed; and the Indus became a British river from Kurrachee to Mooltan, soon to be "red" to its source in the glaciers that fringe Kashgaria. Yet, writing to the Queen on the 27th June, 1843, he formally pronounced his policy "at once just and expedient," after remarking that "it would not be ungrateful to him to be relieved from a government which he has conducted amidst uninterrupted misrepresentations and calumny."

Sind had hardly been disposed of when troubles arose on both sides of the governor-general, who was then at Agra. On the north the disordered kingdom of the Sikhs was threatening the frontier. In Gwalior to the south, the feudatory Mahratta state, there were a strong and large mutinous army, a Ranee only twelve years of age, an adopted chief of eight, and factions in the council of ministers. Instead of citing the authority of the forgotten treaty of Burhanpore, the governor-general might have plead the public security—he did talk of "humanity"—as a reason for demanding that the state should be intrusted to one regent. Our nominee proved incompetent, his rival showed himself a traitor; Tara Ranee was herself little more than a child; and the Prætorians controlled the whole. Ellenborough reviewed the danger in the unanswerable minute of 1st November, 1845, and told Sir Hugh Gough to advance. Further treachery and military license rendered the battles of Maharajpore and Punniar, fought on the same day, inevitable though they were, a surprise to the combatants. The governor-general, on his charger, exposed himself with characteristic rashness in the thick of the fight, and when it was over he regaled the wounded with oranges and gifts. The treaty that followed was as merciful as it was wise. The pacification of Gwalior also had its effect beyond the Sutlej, where anarchy was restrained for yet another year, and the work of civilization was left to Ellenborough's two successors. The idol of the army, he did not leave India without a military banquet, which the duke of Wellington, in an official letter to the earl of Ripon, full of curious reminiscences, refused to condemn. Sir Robert Peel's Government, which had sent him out, made him a viscount and earl, and put him at the head of the Admiralty. When again in his old office, as almost the last president of the Board of Control under Lord Derby, in 1858, he fell into his old impetuosity, by censuring Canning for the confiscation of Oudh, which would have been communistic if it had not proved nominal, and, so far, justified by political reasons. To save the Cabinet he resigned. But for this act of rashness, he might have enjoyed the task of carrying into effect the home constitution for the Government of India which he sketched in his evidence before the Select Committee of the House of Commons on Indian Territories on the 8th June, 1852. Paying off his old score against the East India Company, he then advocated the abolition of the Court of Directors as a governing body, the opening of the Civil Service to the army, the transference of the government to the Crown, and the appointment of a council to advise the minister who should take the place of the president of the Board of Control. These suggestions of 1852 were carried out by his successor Lord Stanley, now earl of Derby, in 1858, so closely, even in details, that Lord Ellenborough must be pronounced the author, for good or evil, of the present home constitution of the Government of India. After his farewell to official life, the dash and the brilliancy of the earl of Ellenborough found a legitimate expression in his vigilant criticisms of Indian, and his broad and eloquent expositions of European, politics in the House of Lords. To the nation he bequeathed, as his only defence, the publication of his letters already referred to, "without introduction or comment." He died at his seat, Southam House, near Cheltenham, on the 22d December, 1871, at the age of eighty-one. The barony reverted to his nephew, the earldom becoming extinct. One of the most able, and certainly the most erratic, of all the governors-general, he survived six of his successors. In many features of his character he resembled his distinguished father.

For the vexed facts of Ellenborough's career, and his always forcibly expressed opinions, see *History of the Indian Administration* (Bentley, 1874), edited by Lord Colchester; *Minutes of Evidence taken before the Select Committee on Indian Territories*, June, 1852; volume i. of the *Calcutta Review*; the *Friend of India*, during the years 1842–45; and a curious little attack on his Gwalior policy by the Maharajah's superintending surgeon, John Hope, *The House of Scindea: A Sketch* (Longmans, 1863). General Colin Mackenzie's pamphlets and Sir John Kaye's writings throw further light on the treatment of the captives. The numerous books by and against Sir Charles Napier, on the conquest of Sind, should be consulted. (G. SM.)

ELLESMERE, Francis Egerton, First Earl of (1800–1857), born in London on the 1st January, 1800, was the second son of the first duke of Sutherland. He was known by his patronymic as Lord Francis Leveson Gower until 1833, when he assumed the surname of Egerton alone, having succeeded on the death of his father to the estates which the latter inherited from the duke of Bridgewater. Educated at Eton and at Christ Church, Oxford, he entered parliament soon after attaining his majority as member for the pocket borough of Bletchingly, in Surrey. He afterwards sat for Sutherlandshire and for South Lancashire, which he represented when he was elevated to the peerage as Earl of Ellesmere and Viscount Brackley in 1846. In politics he was a moderate Conservative of independent views, as was shown by his supporting the proposal for establishing the university of London, by his making and carrying a motion for the endowment of the Roman Catholic clergy in Ireland, and by his advocating free trade long before Sir Robert Peel yielded on the question. Appointed a lord of the treasury in 1827, he held the post of chief secretary for Ireland from 1828 till July, 1830, when he became secretary-at-war. Before the close of the year the administration was broken up, and Lord Francis Leveson Gower did not again hold office. Though he filled a place of some prominence in the political world, his claims to remembrance are founded chiefly on his services to literature and the fine arts. Ere he was twenty he printed for private circulation a volume of poems, which he followed up after a short interval by the publication of a very creditable translation of Goethe's *Faust*, one of the earliest that appeared in England. It was accompanied by some happy translations of German lyrics and a few original poems. In 1839 he visited the Mediterranean and the Holy Land. His impressions of travel were recorded in his very agreeably written *Mediterranean Sketches* (1843), and in the notes to a poem entitled *The Pilgrimage*. He published several other works in prose and verse, all displaying a fine literary taste. His contributions to the *Quarterly Review* were published in a collected form after his death. His literary reputation secured for him the position of rector of Aberdeen University in 1841. Lord Ellesmere was a munificent and yet discriminating patron of artists. To the splendid collection of pictures which he inherited from the duke of Bridgewater he made numerous additions which greatly enriched it, and he built for it a noble gallery to which the public were allowed free access. His benevolence, while unobtrusive, was unfailing, and his manner had the charm of dignified and yet unaffected courtesy. Lord Ellesmere served as president of the Royal Geographical Society and as president of the Royal Asiatic Society. In 1853 he visited the United States as British commissioner to the Great Exhibition at New York. In 1855 he was made a K.G. He was one of the trustees of the National Gallery at the time of his death, which occurred on the 18th February, 1857.

ELLICHPUR (with Melghát), a district of British India, in the commissionership of East Berar, within the Hyderabad Assigned Districts, lies between 20° 51′ and 21° 46′ N. lat. and 76′ 40′ and 78° 30′ E. long. It is bounded on the N. by the Tapti river and the Betul and Chindwárá districts of the Central Provinces, on the E. by the Wardhá river, on the S. by the Amráotí district, and on the W. by the Nimár and Akolá districts. Together with Melghát, it now comprises an area of 2772 square miles, with a population of 344,358, of whom nine-tenths are Hindus. The entire northern half of the district consists of a succession of hills and valleys known as the Melghát or Gáwilgarh hills, a section of the Sátpurá Mountains. The main ridge or watershed of the Sátpurás runs through the district from east to west, attaining its greatest elevation at Bairát, 3987 feet above sea-level. The southern portion of the district is flat, and drained by numerous small streams flowing into the Wardhá and Purná rivers. The only metalled road is that from Amráotí to Ellichpur; but there are several other country roads, and fair weather tracks from village to village passable for eight months in the year. In the hill country, the chief passes are Mallárá on the east and Dúlghát and Bingárá on the west, none of which, however, are practicable for wheeled vehicles. The principal agricultural products are rice and wheat (of excellent quality), gram, pulses, and oilseeds, and these, together with *ghi* and forest timber, comprise the chief exports of the district. The imports are mainly English and country cloth, iron and copper utensils, tobacco, salt, sugar, etc. Ellichpur, the principal town, contains a population of 27,782. It was formerly the capital of the Mahometan governors of the Deccan, and a place of considerable importance.

ELLIOTSON, Dr. John, was born at Southwark, London, towards the end of the last century. He studied medicine first at Edinburgh and then at Cambridge, in both which places he took the degree of M.D., and subsequently at the Borough Hospitals in London. In 1817 he obtained the post of assistant physician, and six years later that of physician, at St. Thomas's Hospital. He there introduced clinical lecturing, a practice which, except at the London Hospital, was at the time nowhere in vogue in the metropolis. In 1831 he ceased lecturing at St. Thomas's, and was elected professor of the principles and practice of physic in London University; in 1834 he resigned the physicianship of the former institution, and accepted a similar post at the North London Hospital. In 1837 he espoused the cause of mesmerism, and thus eventually brought himself into collision with the medical committee of the hospital, a circumstance which led him, on December 28, 1838, to resign the offices held by him there and at the university. In spite of the discouragements he had received, he continued the practice of mesmerism, and became in 1849 physician of a mesmeric infirmary. He died July 29, 1868. Dr. Elliotson was the discoverer of the communicability of glanders to the human subject, the treatment of neuralgia by acupuncture, and the fact that pain does not necessarily continue till death in cases of perforation or rupture of the stomach; he was the first to prove the value of quinine as an antiperiodic, of strong solution of silver nitrate in erysipelas, of prussic acid in gastrodynia and vomiting (*Lancet*, 1827, xi. p. 671), and as a means of preparing the stomach for other medicines, of cupric sulphate in chronic diarrhœa, and of creasote, potassium iodide, and ferrous carbonate in other diseases; and he was moreover one of the earliest among British physicians to advocate the employment of the stethoscope.

He wrote a translation of Blumenbach's *Institutiones Physiologicæ*, 1817; *Cases of the Hydrocyanic or Prussic Acid*, 1820; *Lectures on Diseases of the Heart*, 1830; *Principles and Practice of Medicine*, 1839 (2d ed. 1842), a work which has been translated into several languages; *Human Physiology*, 1840; and *Surgical Operations in the Mesmeric State without Pain*, 1843. He was the author of numerous papers in the *Transactions* of the Medico-Chirurgical Society, of which he was at one time president; and he also edited a mesmeric journal, *The Zoist*. He was a fellow both of the Royal College of Physicians and Royal Society, and the founder and president of the Phrenological Society.

ELLIOTT, Ebenezer (1781–1849), the corn-law rhymer, was born at Masborough, Yorkshire, on the 17th of March, 1781. His father Ebenezer, a man of vigorous intellect, but bigoted in his theological tendencies, exercised a powerful sway over the mind of the future poet. At school Ebenezer was considered a dull pupil; and his childhood was solitary. A touching autobiographic fragment, which appeared after his death in the *Athenæum* for 1850, and is republished in Watkins's life of the poet, gives a deeply interesting account of his early years. His imagination had an unhealthy craving for the horrible, and gloated over the faces of those who had died a violent death, till he was cured by the sight of a body floating in a canal, in an advanced state of decomposition. A more pleasing part of the autobiography tells of his passion for making models of ships, kites, etc. In a very important sense the child was father of the man in Elliott's case, for "even in those days," he says, "I was a free trader, though I knew it not." His father, exasperated at Ebenezer's persistent indolence at school, put him into the foundry with which he was himself connected, where the manufacturing processes interested him. The sight of some fine botanical plates in Sowerby's *English Botany* led him to love flowers, and to gather them as copies for drawing, although not to a taste for botany, "the classifications of which seemed to be like preparations for sending flowers to prison" (*Autobiography*). In his Sunday rambles he encountered a snake, which fascinated him so much that he visited it weekly, and called it "my first snake-love." This is probably the new form his love for what is generally considered loathsome assumed. These walks, by bringing him into contact with the beauty and freshness of nature, proved the foundation of his passion for poetry, which was first gratified by his brother Giles reading Thomson's *Seasons* aloud to him. Acting on his first impulse, he rushed out into the garden to verify the description of the polyanthus and auricula; and his earliest poetic effusion was an imitation of Thomson. He now set about a systematic study of English grammar, but was greatly hindered by a memory singularly defective for rules and classifications, although so strong in other respects that he "almost knew the Bible by heart" when he was twelve years old, and could repeat three books of the *Paradise Lost* when he was sixteen. About the end of Ebenezer's fourteenth year, a poor curate called Firth bequeathed his library to Mr. Elliott—a circumstance which had a great influence on the development of the poet's genius. Barrow, Young, Shenstone, and Milton were special favorites; and after he had studied them thoroughly, Shakespeare, Ossian, Junius, Schiller's *Robbers*, and Gibbon's *Decline and Fall* were eagerly read. Elliott's first published poem, *The Vernal Walk*, was soon followed by *Night, or the Legend of Wharncliffe*, and the *Tales of Night*, embracing *Bothwell* and the *Exile*, dedicated respectively to Southey and Bulwer. Another volume contained *Love*, *The Letter*, *They Met Again*, and *Withered Wild Flowers*. Then came the epic fragment entitled *Spirits and Men*. The fruits of his thoughts on political subjects were seen in the *Ranter* and the *Corn-Law Rhymes*, of which a third edition appeared in 1831. His other important poems are *The Village Patriarch* (1831), *The Splendid Village*, and the *Corn-Law Hymns*. Many gems are to be found among his *Miscellaneous Poems*; but the dramas entitled *Kerhonah* and *Taurassdes* are the least happy of his productions. After his death appeared *More Prose and Verse* in two volumes. His chief works were published between 1830 and 1836. He carried on business as an iron founder in Sheffield for 20 years (1821-41), in which he was so successful that he retired to an estate at Great Houghton, near Barnsley, in 1841, where he resided till his death, which took place on the 1st of December, 1849. A few weeks before he died, his daughter was married to John Watkins, his future biographer. Elliott lives in history by his determined opposition to the "bread-tax," as he called the corn laws, the sad results of which he expressed in such terribly vivid lines as the following:—

> "I bought his coffin with my bed,
> My gown bought earth and prayer;
> I pawn'd my mother's ring for bread,
> I pawn'd my father's chair."

Even when he reached comparative affluence himself, he remained the sturdy champion of the poor, whose representative in the *Rhymes* says:—

> "And workhouse bread ne'er crossed my teeth,—
> I trust it never will."

Elliott's poetry is stamped throughout by the grandeur of his personal character. Transparent sincerity and passionate earnestness meet us in every page. His poems are beautifully described by Carlyle as "hues of joy and harmony, painted out of troublous tears." To be a reformer of the world was his ambition; and the purely literary spirit, which looks at life mainly as affording materials for artistic conceptions, was utterly foreign to his nature. Crabbe's genius cast a spell over Elliott; although it can scarcely be said that a man of such rugged originality was a slavish imitator of any one. His works reflect the joy with which a poet escapes from the smoke, glare, and noise of city life to drink in the sweet air of country lanes and fields. Yorkshire scenery especially is embalmed in his verse. Although Elliott had no great respect for theological dogma, there is a genuine religious vein in his poetry. His works have engaged the pens of men endowed with loftier literary genius than his own, including Professor Wilson, Southey, Bulwer, and Carlyle.

In addition to the life by Watkins, there is a biography by January Searle; and an edition of his poems has been issued by his son, the Rev. Edwin Elliott of St. John's, Antigua.

ELLIS, George (1745–1815), a miscellaneous writer distinguished for his services in promoting a knowledge of early English literature, was born in London in 1745. Educated at Westminster School and at Trinity College, Cambridge, he commenced his literary career as a contributor to the *Rolliad* and the *Probationary Odes*, political satires directed against Pitt's administration. He was afterwards, however, on friendly terms with Pitt, and in 1797 he accompanied Lord Malmesbury to Lille as secretary to the embassy. He found continued scope for his power as a political caricaturist in the columns of the *Anti-Jacobin*, to which he was, next to Canning and Frere, perhaps the most brilliant contributor. For some years before the *Anti-Jacobin* was started Ellis had been working in the congenial field of early English literature, in which he was one of the first to awaken a new interest. The first edition of his *Specimens of the Early English Poets* appeared in 1790; an enlarged edition in three volumes was published in 1801. This was followed by *Specimens of Early English Romances in Metre* (3 vols., 1805). Hallam speaks of his "good taste in selection;" and his skill as editor and interpreter was of much service to less learned readers than himself. Ellis was an intimate friend of Sir Walter Scott, who styled him "the first converser I ever saw," and dedicated to him the fifth canto of *Marmion*. He died on the 15th April, 1815. The monument erected to his memory in the parish church of Gunning Hill, Berks, bears a fine inscription from the pen of Canning.

ELLIS, Sir Henry (1777–1869), a distinguished antiquarian writer, for many years principal librarian to the British Museum, was born in London of a Yorkshire family in 1777. He was educated at the Merchant Taylors' School, and at St. John's College, Oxford, where he took his degree and obtained a fellowship. After having held for a few months a sub-librarianship in the Bodleian, he was appointed to a similar post in the British Museum in 1800. In 1827 he became chief librarian, and he discharged the duties of the office with great efficiency and urbanity until 1856, when he resigned on account of advancing age. During the reign of William IV. he was made a knight of Hanover. He died on the 15th January, 1869. Sir Henry Ellis's life was one of very considerable literary activity. His first work of importance was the preparation of a new edition of Brand's *Popular Antiquities*, which appeared in 1813. In 1816 he was selected by the Commissioners of Public Records to write the introduction to Domesday Book, a task which he discharged with much learning, though several of his views have not stood the test of later criticism. His *Original Letters Illustrative of English History* (first series, 1824; second series, 1827) are compiled chiefly from manuscripts in the British Museum and the State Paper Office, and have been of considerable service to historical writers. To the Library of Entertaining Knowledge he contributed four volumes on the Elgin and Townley Marbles. Sir Henry was for many years joint-secretary of the Society of Antiquaries.

ELLIS, William (1794–1872), one of the most devoted and successful of modern missionaries, was born in London on the 29th August, 1794. When he was about four years old his father, who was a workingman, removed with his family to Wisbeach, where accordingly his boyhood was spent. His school education was even scantier than boys of his class at that time usually received, but being naturally bright and intelligent he did much to supply the deficiency by his own efforts. When about twelve years of age he was put to work with a market gardener. He showed an enthusiastic interest in gardening work, and continued to be engaged in it under various employers until 1814. In that year having come under serious religious impressions, he offered himself as a missionary to the London Missionary Society, and after due inquiry the offer was accepted. The year which was allowed him for training was devoted not merely to the study of theology at Homerton, but to the acquisition of various practical arts, such as printing and bookbinding, which proved of the utmost service to him in the mission field. Having been ordained, he sailed for the South Sea Islands in January, 1816, and reached his destination after a voyage of thirteen months' duration. He remained in Polynesia, occupying various stations in succession, until 1824, when he was compelled to return home on account of the state of his wife's health. Though the period of his residence in the island was thus comparatively short, his labors were very fruitful, contributing perhaps as much as those of any other missionary to bring about the extraordinary improvement in the religious, moral, and social condition of the Southern Archipelago that has taken place during the present century. He was not only unwearied in his efforts to promote the immediate spiritual object of his mission, but he introduced many secondary aids to the improvement of the condition of the people. His gardening experience enabled him successfully to acclimatize many species of tropical fruits and plants, which now form an important source of wealth to the islanders; and he had the distinction of setting up and working the first printing-press in the South Seas. Ellis and his wife availed themselves for their journey home of an American vessel, which landed them free of all charge at New Bedford, Massachusetts, in the spring of 1825. They remained for some months in the United States, where they were exceedingly well received, and Ellis excited much interest in the mission with which he was connected by attending numerous public meetings held in support of its claims. For several years after his return to England, he was employed as a travelling agent of the London Missionary Society, whose schemes he explained and advocated in nearly every important town of the United Kingdom. In the midst of this busy life he found time to publish his *Tour through Hawaii* (1826), which had been written in the course of his journey home, and his *Polynesian Researches* (2 vols., 1829), a work which Southey in the *Quarterly Review* characterized as one of the most interesting he had ever read. In 1832 he was appointed foreign secretary to the London Missionary Society, the state of his wife's health rendering the long-cherished prospect of a return to the South Seas hopeless. He discharged the duties of the office with great efficiency for seven years, when threatened cerebral disease compelled him to resign it. In the interval his first wife had died, and he had married in 1837 Miss Sarah Stickney, authoress of *The Poetry of Life*, *The Women of England*, and many other well-known works. Just before resigning the secretaryship he published his *History of Madagascar*, and thus first established between his name and that island a connection which was destined to be honorable and enduring in no common degree. After a season spent in Pau, of which Mrs. Ellis has given a most interesting account in her *Summer and Winter in the Pyrenees*, Mr. Ellis and his wife returned to England in 1841, and took up their residence in a beautiful country house at Rose Hill, Hoddesdon, Hertfordshire. Here he continued to show unabated interest and almost unabated activity in the business of the society with which he had been in one capacity or another so long connected. By desire of the directors he undertook a history of the society, the first volume of which appeared in 1844, though pressure of other work prevented its completion. In 1847 he accepted the pastorate of the little Congregational church at Hoddesdon, which had been revived and strengthened mainly through his exertions. After a few years his quiet life was interrupted by a call from the London Missionary Society to proceed to Madagascar in order to inquire into the prospects for the resumption of the missionary enterprise there, which had been checked for several years owing to the bitter hostility of the reigning queen. Between 1853 and 1857 he paid three visits to that island, of which he has given a full account in his *Three Visits to Madagascar* (1858), one of the most profoundly interesting and romantic narratives in the whole literature of missions. In reading it one scarcely knows whether to admire most the fearlessness, the undeviating regard for principle, or the discretion, with which he discharged a most delicate and difficult negotiation, and won in the end a signal triumph for free Christianity. Though its primary interest is religious, the work contains much valuable scientific information. At the invitation of the directors of the society, Ellis undertook another journey to Madagascar in 1863, when he was close upon seventy years of age. Of this he gave an account in his *Madagascar Revisited* (1867). He died on the 25th June, 1872. In addition to the works already mentioned, Ellis was the author of *A Vindication of the South Sea Missions from the Misrepresentations of Otto Von Kotzebue* (1831), and *Village Lectures on Popery* (1851).

Mrs. Ellis survived her husband only a few days. For a considerable number of years she conducted a ladies' school in Hertfordshire on principles which she had carefully thought out, and which are explained in her *Rawdon House* (1848). She wrote upwards of thirty works, most of which were very popular.

ELLOR, or Ellur, a town of British India, in the Godávarí district, in the presidency of Madras, situated on the bank of the Tammaler river, in 16° 43′ N. lat. and 81° 10′ E. long. The town contains a population of 25,487 persons, made up as follows: Hindus, 20,253; Mahometans, 5046; Christians, 188. Ellor is a municipality, and the chief town of the *táluk* or sub-district of the same name. The town, which is clean and healthy, with well-shaded roads, is the headquarters of an executive engineer, with magisterial and civil courts, post-office, school, etc.; it is also a station of the Church Missionary Society and of the Lutheran Mission. The municipal income in 1875–76 amounted to £769, and the expenditure to £957. The chief industry of the place is the manufacture of woollen carpets. Ellor was formerly a military station.

ELLORÁ, a town of India, in the native state of Hyderabad, near the city of Dowletabad, situated in 20° 2′ N. lat. and 75° 13′ E. long. In a mountain near this town there are some remarkable excavations, containing mythological symbols of the Hindu worship, and temples ornamented with statues of many of the deities. The principal figures are those of Indra, the god of the firmament, and his consort Indráni. Besides these, there are some figures of the deities and incarnations adored by the Jains, the followers of Buddha and Parisnáth; but all of them have been forsaken by the priests. The temple is said to have been executed by Rájáh Edu of Ellichpur, who was cured of a cutaneous disorder by a spring near the place, and in gratitude gave orders for the construction of the shrine. It measures 138 feet in front, and in the interior extends 247 feet in length by 150 feet in breadth, and is in some places 100 feet high. A minute account of these curious antiquities is contained in the sixth volume of the *Asiatic Researches* and in Fergusson's *History of Indian and Eastern Architecture.* See also article Architecture, vol. ii. pp. 345, 346. Ellora was ceded in 1818 by Holkar to the British, who transferred it to the Nizám in 1822 by the treaty of Hyderabad.

ELLSWORTH, a city of the United States, capital of Hancock county, Maine, is situated 25 miles east of Bangor, on the Union river, about four miles from its mouth. As the port of entry for the district of Frenchman's Bay, and the seat of an extensive trade in timber, it enjoys great commercial prosperity; and, besides a considerable variety of wooden wares, it manufactures iron, brass, sailcloth, carriages, and sledges. Population in 1840, 2263; in 1870, 5257.

ELLWOOD, Thomas (1639–1713), an English author, chiefly celebrated from his connection with Milton, was born at Crowell, in Oxfordshire, in 1639. The principal facts of his life are related in a very interesting autobiography, which contains much information as to his intercourse with the poet. While he was still young his father removed to London, where Thomas became acquainted with a Quaker family named Pennington, and was led through their influence to connect himself with the Society of Friends. The change was very distasteful to his father, and the autobiography gives a full account of the persecution to which he was subjected on account of it. It was through the Penningtons that he was introduced in 1661 to Milton in the capacity of Latin reader. He spent nearly every afternoon in the poet's house in Jewin street, until the intercourse was interrupted by an illness which compelled him to go to the country. After a period of imprisonment at Aylesbury for Quakerism, Ellwood resumed his visits to Milton, who was now residing at a house his Quaker friend had taken for him at Giles Chalfont. It was during this residence in the country that the poet gave him the manuscript of the *Paradise Lost* to read, and did him the honor of asking his opinion of it. In returning the manuscript Ellwood suggested "Paradise Found" as a subject; and when Milton long afterwards in London showed him *Paradise Regained*, it was with the remark, "This is owing to you, for you put it into my head at Chalfont." Ellwood was the author of several polemical works, of which *Forgery no Christianity* (1674) and *The Foundation of Tithes Shaken* (1682) deserve mention. His *Sacred Histories of the Old and New Testaments* appeared in 1705 and 1709. He died in 1713. His autobiography was published in the following year. Another edition appeared in 1791.

ELM, the popular name for the trees and shrubs constituting the genus *Ulmus*, of the natural order *Ulmaceæ*. The Common Elm, *U. campestris*, a doubtful native of England, is found throughout great part of Europe, in North Africa, and in Asia Minor, whence it ranges as far east as Japan. It grows on almost all soils, but thrives best on a rich loam, in open, low-lying, moderately moist situations, attaining a height of 60–100, and in some few cases as much as 130 or 150, feet. The branches are numerous and spreading, and often pendulous at the extremities; the bark is rugged; the leaves are alternate, ovate, rough, doubly serrate, and, as in other species of *Ulmus*, unequal at the base (see vol. iv. p. 98, fig. 100); the flowers are small, hermaphrodite, numerous, in purplish-brown tufts, and each with a fringed basal bract, have a four-toothed campanulate calyx, four stamens, and two styles, and appear before the leaves in March and April; and the seed-vessels are green, membranous, one-seeded, and deeply-cleft. Unlike the wych elm, it rarely perfects its seed in England, where it is propagated by means of suckers from old trees, or preferably by layers from stools. In the first ten years of its growth it ordinarily reaches a height of 25–30 feet. The wood, at first brownish-white, becomes, with growth, of a brown color having a greenish shade. It is close-grained, free from knots, without apparent medullary rays, and is hard and tough, but will not take a polish. All parts of the trunk, including the sapwood, are available in carpentry. By drying, the wood loses over 60 per cent. of its weight, and has then a specific gravity of 0·588. It has considerable transverse strength, does not crack when once seasoned, and is remarkably durable under water, or if kept quite dry; though it decays rapidly on exposure to the weather, which in ten to eighteen months causes the bark to fall off, and gives to the wood a yellowish color—a sign of deterioration in quality. To prevent shrinking and warping it may be preserved in water or mud, but it is best worked up soon after felling. Analyses of the ash of the wood have given a percentage of 47·8 per cent. of lime, 21·9 per cent of potash, and 13·7 per cent of soda. In summer, elm trees often exude an alkaline gummy substance, which by the action of the air becomes the brown insoluble body termed *ulmin.* Elm wood is used for keels and bilge-planks, the blocks and dead-eyes of rigging, and ships' pumps, for coffins, wheels, furniture, carved and turned articles, and for general carpenters' work; and previous to the common employment of cast iron was much in request for water-pipes. The inner bark of the elm is made into bast mats and ropes. It contains mucilage, with a little tannic acid, and was formerly much employed for the preparation of an antiscorbutic decoction, the *decoctum ulmi* of pharmacy. The bark of *Ulmus fulva*, Michaux, the Slippery or Red Elm of the United States and Canada, serves the North American Indians for the same purpose, and also as a vulnerary. The leaves as well as the young shoots of elms have been found a suitable food for live stock. For ornamental purposes elm trees are frequently planted, and in avenues, as at the park of Stratfieldsaye, in Hampshire, are highly effective. They were first used in France for the adornment of public walks in the reign of Francis I. In Italy, as in ancient times, it is still customary to train the vine upon the elm—a practice to which frequent allusion has been made by the poets. Among the small-leaved varieties of *U. campestris* are the species *U. Berardi* and *U. fastigiata;* besides these there are several slender kinds with variegated leaves.

The Wych Elm or Wych Hazel, *U. montana*, is indigenous to Britain, where it usually attains a height of about 50 feet, but among tall-growing trees may reach 120 feet. It has drooping branches, and a smoother and thinner bark, larger and more tapering leaves, and a far less deeply notched seed-vessel than *U. campestris.* The wood, though more porous than in that species, is a tough and hard material when properly seasoned, and, being very flexible when steamed, is well adapted for boat-building. Branches of the wych elm were formerly manufactured into bows (see vol. ii. p. 325), and if forked were employed as divining-rods. The Weeping Elm, the most ornamental member of the genus, is regarded as a variety of this species. The Dutch or Sand Elm is a tree very similar to the wych elm, but produces inferior timber. The Cork-Barked Elm, *U. suberosa*, is distinguished chiefly by the thick deeply-fissured bark with which its branches are covered. The American or White Elm, *U. americana*, is a hardy and very handsome species, of which the old tree of Boston Common (U. S.) was a representative. This tree is supposed to have been in existence before the settlement of Boston, and at the time of its destruction by the storm of the 15th February, 1876, measured 22 feet in circumference.

See Arboriculture, vol. ii. p. 278; Loudon, *Arboretum Britannicum*, vol. iii. 1838.

ELMACIN, Elmacinus, or Elmakyn, George (1223–1273), author of a history of the Saracens, and known in the East by the name of Ibn-Amid, was a Christian of Egypt, where he was born in the year 1223. He occupied the place of ketib or secretary at the court of the sultans of Egypt, an office which was usually filled by Christians. His history consists of annals which extend from the time of Mahomet till the year 1117. It is principally occupied with the affairs of the Saracen empire, but contains some passages relating to the Eastern Christians. In 1238 he succeeded his father, Yaser Al Amid, who had held the office of secretary to the council of war under the sultans of Egypt for forty-five years. Elmacin died at Damascus in 1273. His history was published, in Arabic and Latin, at Leyden in 1625. A reprint of the Latin version was published soon afterwards, and was followed by a French translation. A complete edition containing only the Arabic text is in use among the Christians of the Levant.

ELMES, Harvey Lonsdale (1814–1847), the architect of St. George's Hall, Liverpool, was the son of James Elmes (see next article), and was born at Chichester in 1814. After serving some time in his father's office, and under a surveyor at Bedford and an architect at Bath, he became partner with his father in 1835, and in the following year he was the successful competitor among 86 for a design for St. George's Hall, Liverpool. The foundation stone of this building was laid on the 28th June, 1838, but Elmes being successful in a competition for the Assize Courts in the same city, it was finally decided to include the Hall and Courts in a single building. In accordance with this idea, Elmes prepared a fresh design, and the work of erection commenced in 1841. He superintended its progress till 1847, when from failing health he was compelled to delegate his duties to C. R. Cockerell, R. A., and leave for Jamaica, where he died of consumption on the 26th November, 1847.

ELMES, James (1782–1862), father of the preceding, an architect, civil engineer, and writer on the arts, was born in London, 15th October, 1782. He was educated at Merchant Taylors' School, and, after studying building under his father, and architecture under Mr. George Gibson, became a student at the Royal Academy, where he gained the silver medal in 1804. He designed a large number of buildings in the metropolis, and was surveyor and civil engineer to the port of London, but is best known as a writer on the arts. In 1809 he became vice-president of the Royal Architectural Society, but this office, as well as that of surveyor of the port of London, he was compelled through partial loss of sight to resign in 1828. He died at Greenwich, April 2, 1862.

Besides contributing largely to periodical literature, he is author of *Sir Christopher Wren and his Times* (1823), *Lectures on Architecture* (1823), *The Arts and Artists* (1825), *General and Biographical Dictionary of the Fine Arts* (1826), *Treatise on Architectural Jurisprudence* (1827), and *Thomas Clarkson: a Monograph* (1854).

ELMINA, a town and fort on the Gold Coast, Upper Guinea, West Africa, now a British possession, is situated on a peninsula bounded on the north by the River Benyan or Beyuh, about six miles west of Cape Coast Castle, in 5° 4′ 45″ N. lat. and 1° 20′ 30″ W. long. The streets of the native town are narrow and dirty, but there are a considerable number of neat and spacious cottages, occupied by the officials and merchants. The inhabitants are chiefly merchants and their servants, fishers, and mechanics. The river could at one time be entered by schooners, but on account of a bar having formed at its mouth it is now accessible only to small boats. Elmina is the earliest European settlement on this coast, and was established by the Portuguese as early as 1481, under the name of São-Jorge da Mina. Soon after landing they commenced to build the castle now known under the name of Fort St. George, but it was not completed till eighty years afterwards. Another defensive work is Fort St. Ingo, built in 1666, which is behind the town and at some distance from the coast. Elmina was captured by the Dutch in 1637, and ceded to them by treaty in 1640. Along with the Dutch possessions on the Guinea Coast, it was, in return for certain commercial privileges, transferred to Great Britain, April 6, 1872. The king of Ashantee, claiming to be its superior, objected to its transfer, and the result was the Ashantee war. During this war the king's quarter was bombarded and laid in ruins by the British, June 13, 1873. The population of Elmina is about 10,000.

ELMIRA, a city of the United States, capital of Chemung county, New York, is situated in a fertile valley on the Chemung river, and on the Erie and Northern Central railroads, 274 miles W. N. W. of New York. By the Chemung Canal it is connected with Seneca Lake, 20 miles distant, and by the Junction Canal with the interior of Pennsylvania. Its principal buildings are the fine court house, the female college, attended by about 120 students, the high and normal schools, and the free academy. It has iron and steel works, breweries, tanneries, and manufactories of boots and shoes, edge tools, and pianos. Elmira was settled in 1788, was incorporated as a village under the name of New Town in 1815, received its present name in 1828, and obtained a city charter in 1864. The population in 1870 was 15,863.

EL-OBEID, Lobeid or Obeidh, the chief town of the country of Kordofan, in Africa, and the seat of an Egyptian governor, is situated at a height of 1700 feet above the sea, at the foot of Jebel Kordofan, about 150 miles west of the Bahr-el Abiad, or White Nile, in 13° 15′ N. lat. and 30° 7′ E. long. It is scattered over a large area, and in fact consists of several distinct townships, each inhabited by a different race. Most of the houses are mere mud huts, which require to be rebuilt or extensively repaired every year after the rainy season; but, besides the governor's residence, there are three barracks, a gunpowder magazine, a hospital, and six mosques. Strong fences of thorny brushwood have to be maintained by every household as a protective against the wild beasts that invade the town by night. Though the wells have been sunk to a depth of nearly 100 feet, water is frequently scarce. The inhabitants make plaited work of palm-leaf fibres and beautiful silver filigree; and a considerable trade is carried on in gum, gold, and ivory with Darfur and other neighboring countries. The population is estimated at from 12,000 to 20,000.

ELOI, St. (588–659), originally a goldsmith, but afterwards bishop of Noyon, was born at Cadillac, near Limoges, in 588. Having manifested at an early age a decided talent for the art of design, he was placed by his parents with the master of the mint at Limoges, where he made rapid progress in goldsmith's work. He became coiner to Clotaire II. of France, and treasurer to his successor Dagobert. Both kings intrusted him with important works, among which were the composition of the bas-reliefs which ornament the tomb of St. Germain, bishop of Paris, and the execution (for Clotaire) of two chairs of gold, adorned with jewels, which at that time were reckoned *chefs d'œuvre.* Though he was amassing great wealth, Eloi acquired a distaste for a worldly life, and resolved to become a priest. At first he retired to a monastery, but in 640 was raised to the bishopric of Noyon. He made frequent missionary excursions to the pagans of Brabant, and also founded a great many monasteries and churches. He died 1st December, 659.

His life has been written by his friend and contemporary St. Ouen; and a French translation of this life by the Abbé La Roque, together with 16 homilies said to have been written by St. Eloi, was published at Paris in 1693.

EL PASO, or El Paso del Norte, a town of Mexico, in the state of Chihuahua, situated on the Rio Grande, in a narrow valley near the frontier of New Mexico, 340 miles W. S. W. of Santa Fé, 31° 42′ N. lat., 106° 40′ W. long. The name is often applied to a whole group of small settlements on the Rio Grande, but belongs properly to the largest of their number, which owes its origin to the establishment of a military post. It is situated in the chief thoroughfare between New Mexico and Chihuahua. The town is a mere collection of brick huts without windows, and with earthen floors. In the district the vine is largely cultivated, and wine and brandy are manufactured. On account of the fertility of the soil the inhabitants enjoy an abundance of material luxuries, but they are totally ignorant of most of the appliances of civilized life. The population is about 6000.

ELPHINSTONE, The Honorable Mountstuart. (1779–1859), an eminent Indian statesman, fourth son of the eleventh Baron Elphinstone in the peerage of Scotland, was born in 1779. Having received an appointment in the civil service of the East India Company, of which one of his uncles was a director, he reached Calcutta in the beginning of 1796. After filling several subordinate posts, he was appointed in 1801 assistant to the British resident at Poonah, at the court of the Peishwa, the most powerful of the Mahratta princes. Here he obtained his first opportunity of distinction, being attached in the capacity of diplomatist to the mission of Sir Arthur Wellesley to the Mahrattas. When, on the failure of negotiations, war broke out, Elphinstone, though a civilian, acted as virtual *aide-de-camp* to General Wellesley. He was present at the battle of Assaye, and displayed such courage and knowledge of tactics throughout the whole campaign that Wellesley told him he had mistaken his profession, and that he ought to have been a soldier. In 1806 when the war closed he was appointed British resident at Nagpore. Here, the times being uneventful and his duties light, he occupied much of his leisure in reading classical and general literature, and acquired those studious habits which clung to him throughout life. In 1808 he was placed at the head of a most important political mission to Central Asia, being appointed the first British envoy to the court of Cabul, with the object of securing a friendly alliance with the Afghans in view of a possible French invasion. The negotiations, protracted and difficult, resulted in a treaty securing what the English wished; but it proved of little value, partly because the danger of invasion had passed away, and partly because the Shah Shuja was driven from the throne by his brother before it could be ratified. The most valuable permanent result of the embassy was the literary fruit it bore several years afterwards in Elphinstone's great work on Cabul. After spending about a year in Calcutta arranging the report of his mission, Elphinstone was appointed in 1811 to the important and difficult post of resident at Poonah. The difficulty arose from the general complication of Mahratta politics, and especially from the weak and treacherous character of the Peishwa, which Elphinstone rightly read from the first. While the mask of friendship was kept up Elphinstone carried out the only suitable policy, that of vigilant quiescence, with admirable tact and patience; when in 1817 the mask was thrown aside and the Peishwa ventured to declare war, the English resident proved for the second time the truth of Wellesley's assertion that he was born a soldier. Though his own account of his share in the campaign is characteristically modest, one can gather from it that the success of the English troops was chiefly owing to his assuming the command at an important crisis during the battle of Kirkee. When Poonah fell he humanely exerted himself with almost complete success to prevent a seemingly inevitable sack of the town by the incensed soldiers. The Peishwa being driven from his throne, his territories were annexed to the British dominions, and Elphinstone was nominated commissioner to administer them. He discharged the responsible task with rare judgment and ability. The characteristic feature of his policy was his scrupulous regard for the customs, interests, and wishes of the native population, in so far as these were compatible with the British supremacy. Recognizing the deep-seated conservatism of the Hindu character, he avoided needless change, and sought rather to develop what reforms seemed essential from within than to impose them from without. With this view he preserved as far as possible the native system of administration of justice, and maintained the landholders and chiefs in the possession of their rights and privileges. His conciliatory administration not only drew to him personally the attachment of all classes, but was of the utmost benefit in confirming the British authority in the newly annexed territory, which might easily have been brought by a different policy to throw off the yoke.

So high was Elphinstone's reputation for administrative ability, that, when the lieutenant-governorship of Bombay fell vacant in 1819, the Court of Directors appointed him to the position in preference to two candidates of distinguished merit who were both his seniors. He entered upon his new duties in 1820, and discharged them until 1827, when he was succeeded by Sir John Malcolm. The period was tranquil, and the governor devoted himself to internal reforms with that happy combination of zeal and discretion which always distinguished him. His principal achievement was the drawing up of the Elphinstone code, which for comprehensiveness, clearness, and equity takes a high rank among works of its class. He faithfully carried out the policy of retrenchment prescribed by the East India Company, and it may be noted as characteristic that he commenced his economic reforms by reducing the Government House establishment. His efforts to promote native education, however, had probably more beneficial and far-reaching results than any other department of his activity. He may fairly be regarded as the founder of the system of state education in India, and he probably did more than any other Indian administrator to further every likely scheme for the promotion of native education. Adhering to the policy he had adopted at Poonah of respecting the customs, opinions, feelings, and even—wherever possible—the prejudices of the native population, he won their attachment in quite an exceptional degree. Bishop Heber, who specially admired his zeal in the cause of education, spoke of him as one of the most extraordinary men and certainly the most popular governor that he had fallen in with. Of his popularity remarkable proof was afforded both by natives and Europeans when he resigned his post. The farewell addresses which poured in upon him were almost innumerable; and his connection with the presidency was most appropriately commemorated in the endowment by the native communities of the Elphinstone College, and in the erection of a statue in marble by the European inhabitants of the presidencies.

Elphinstone spent nearly two years on the journey home, visiting Egypt and Palestine, and many of the scenes in Greece and Italy with which he was already familiar as an ardent student of classical literature. On his arrival in England the choice was open to him of a distinguished career in home politics or the highest place in the management of Indian affairs. But he was deficient in ambition, and his health had suffered so much from his residence in

India that he deemed himself disqualified for public life. Accordingly, although the governor-generalship of India was twice offered to him in the most flattering terms within a few years of his return, he declined it on both occasions; and he resisted with equal firmness all attempts to induce him to enter the home parliament. It is understood that he declined the offer of a peerage. The retirement in which he spent the last thirty years of his life, however, was far from being either indolent or dishonorable. He kept up the habit of study he had acquired in India, he made contributions of the highest value to literature, and he preserved until his death the liveliest interest in the affairs of the great empire which had been the scene of his activity. His advice was always taken and generally followed in difficult questions of Indian policy, and he kept up constant communication by correspondence and otherwise with leading Indian administrators, so that his personal influence continued to be an important factor in the government of India almost to the day of his death. He had long before his return from India made his reputation as an author by the work on Cabul already mentioned, which was published in 1815 with the title *An Account of the Kingdom of Cabul and its Dependencies in Persia and India*. Soon after his arrival in England he commenced the preparation of a work of wider scope, a history of India, which was published in 1841. It embraced the Hindu and Mahometan periods, and is generally regarded as a work of the highest authority. Its chief features are thoroughness of research, judicious use of materials, and condensation of style.

Mr. Elphinstone died at his residence at Limpsfield, in Surrey, on the 20th November, 1859. (W. B. S.)

ELPHINSTONE, WILLIAM (1431–1514), a Scottish prelate and statesman of considerable eminence, was born at Glasgow in 1431. He received his education at the grammar school and the university of that city, and took his degree as M.A. about his twentieth year. Having received ordination, he was appointed priest of the church of St. Michael's, Glasgow, an office which he held for four years. He afterwards studied civil and canon law in the university of Paris, where in due time he became professor, and for six years discharged the duties of his office with great reputation. On his return to Scotland on the invitation of Bishop Muirhead, after an absence of nine years, he was successively appointed official of Glasgow, St. Andrews, and Lothian. In the year of his return he was made rector of the university of Glasgow. In 1478 he was admitted a member of the Privy Council; and on the occasion of a misunderstanding between James III. of Scotland and Louis XI. of France, his powerful mediation at the latter court, in conjunction with the bishop of Dunkeld and the earl of Buchan, effected an amicable reconciliation. For the diplomatic ability which Elphinstone on this occasion displayed the king rewarded him with the see of Ross, from which he was translated to that of Aberdeen about 1484. He subsequently held the office of chancellor of the kingdom; and besides carrying on negotiations with the English king, he acted as mediator between James and the discontented nobility. During his residence at Aberdeen, Elphinstone appears to have declined all interference with public affairs of a political nature, and to have confined himself to the discharge of his episcopal duties. But when James IV. ascended the throne, he was chosen in 1488 ambassador to the emperor Maximilian, in order to negotiate a marriage between his royal master and the emperor's daughter. The bishop's mission failed in the object for which it was set on foot, but was the means of terminating an enmity which had long existed between the Dutch and Scots. The masterly manner in which he conducted this affair raised him in the estimation of James, who generally consulted him and followed his advice in every affair of importance. From 1492 till the close of his life he held the office of lord privy seal. Elphinstone was also a zealous patron of learning. It is generally believed that the establishment of a university at Aberdeen was entirely owing to his influence with the pope, from whom he obtained a bull for that purpose; and it was almost entirely by his exertions that King's College was undertaken and completed. At his death, which took place on the 25th October, 1514, at the advanced age of eighty-three, he bequeathed a sum of 10,000 pounds Scots for its erection and endowment, as well as for the maintenance of a bridge over the Dee. Besides a history of Scotland, now preserved among the Fairfax MSS. in the Bodleian Library, Elphinstone wrote a book of canons and some lives of Scottish saints.

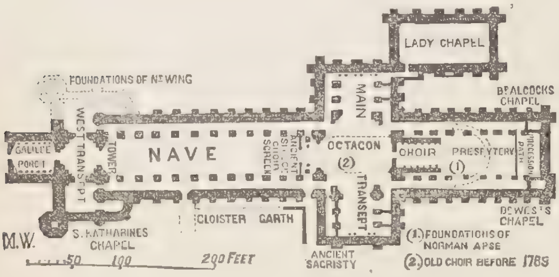
EL ROSARIO, a town of Mexico, in the state of Xinoloa, 55 miles east of Mazatlan. At one time its gold and silver mines attracted a large number of diggers, but they are no longer wrought, and it is now of importance chiefly as a dépôt for the trade with Mazatlan and the interior. Population about 5000.

ELSINORE, or ELSINEUR (Danish HELSINGOR), a seaport town of Denmark, is situated in the district of Frederiksborg, on the east coast of the island of Seeland, 56° 2′ N. lat., 12° 38′ E. long. It stands at the narrowest part of the Sound, opposite the Swedish town of Helsingborg, which is only about three miles distant, and with which the means of intercourse are ample. The town is well built, but its streets are somewhat irregular. Until 1857, Sound dues were paid to it by all foreign vessels, except those of Sweden, going to or from the Baltic. Its harbor is small, but the roadstead affords excellent anchorage, which is largely taken advantage of by shipmasters detained by adverse winds. Its import and export trades are gradually increasing, coal comprising the chief portion of the former, and the latter being principally the supply of provisions to passing ships. Elsinore was raised to the rank of a town in 1425. In 1522 it was taken and burnt by Lübeck, but in 1535 was retaken by Christian II. It is celebrated as the scene of Shakespeare's tragedy of *Hamlet*, and it was the birth-place of Saxo-Grammaticus, from whose history the story of Hamlet is derived. A pile of rocks surrounded by trees is yet shown to travellers as the grave of Hamlet, and Ophelia's brook is also pointed out, but both are of course mere inventions. On a tongue of land east of the town stands the castle of Kronberg or Kronenberg, a magnificent, solid, and venerable Gothic structure built by Frederick II. towards the end of the 16th century. It was taken by the Swedes in 1658, but its possession was again given up to the Danes in 1660. Its strength has been increased greatly by modern fortifications, and it has accommodation for 1000 men. From its turrets, one of which serves as a lighthouse, there are fine views of the straits and of the neighboring countries. Within it the principal object of interest is the apartment in which Matilda, queen of Christian VII. and sister of George III. of England, was imprisoned before she was taken to Hanover. North-west of the town is Marienlyst, originally a royal château, but now a hotel and bathing establishment. The population of Elsinore in 1870 was 8891.

ELVAS (the ancient *Helvas*), a fortified frontier city of Portugal, in the Portalegre district of the province of Alemtejo, is situated near a sub-tributary of the Guadiana, on a hill belonging to the mountain chain of Zoledo, 105 miles east of Lisbon and 10 miles west of the Spanish town of Badajoz, with which towns it is connected by railway. Its streets are winding, narrow, and dirty, and many of the Moorish buildings which gave the town a somewhat venerable aspect are fast crumbling to ruins. It is the seat of a bishopric, and has four parish churches, one of which is a cathedral, seven conventual buildings, a theatre, an arsenal, and a hospital. It is supplied with water by means of a large Moorish aqueduct. It carries on a large contraband trade with Spain, especially in articles of English manufacture; and has also manufactories for hardware and jewelry. The surrounding country is very fruitful, and affords large supplies of oil, wine, and vegetables. Elvas is the largest and strongest fortress of Portugal. It is defended by seven bastions which surround the town, and by two forts—Santa Luzia and Nostra Senhora da Graça—which command the whole neighborhood. Elvas was a place of great importance during the Peninsular war. It was taken by Marshal Junot in March, 1808, and held by the French till August, when it was given up in terms of the convention at Cintra. The population in 1869 numbered 11,088.

ELY, a city of Cambridgeshire, is situated on a considerable eminence in the Isle of Ely, near the Ouse, 16 miles N.N.E. of Cambridge. It consists chiefly of one long street, and the houses are mostly old. The soil in the vicinity is very fertile, and is cultivated chiefly by market gardeners, who send large quantities of fruit and vegetables to the London market. The town has a considerable manufactory for earthenware and tobacco pipes, and there are several mills in the isle for the preparation of oil from flax, hemp, and cole-seed. The market-day is Thursday. Besides the churches and the cathedral, the chief public buildings are the grammar-school founded by Henry VIII., the new corn exchange, the mechanics' institute, and the sessions house. Needham's charity school has recently been developed into a considerable school of the second grade. The national and infant schools are large and commodious. A monastery was founded here about 670; but in 870 it was pillaged and destroyed by the Danes, and it remained in ruins till 970, when it was restored by Ethelwold, bishop of Winchester. In 1107 Ely was erected into a bishopric by Henry I., and after the dissolution of the monasteries, Henry VIII. converted the conventual church into a cathedral. This edifice displays a singular mixture of various styles of architecture, and has an unfinished appearance, but taken as a whole it is a noble structure. The nave, which is Late Norman, was probably completed about the middle of the 12th century, and the western tower and the transepts were built by Bishop Ridal (1174–1189). The Galilee or western porch, which is Early English, was erected by Bishop Eustace (1198–1215). The choir was originally Early Norman, but its Norman apse was destroyed, and the church extended eastward by six more arches, by Bishop Northwold, about the middle of the 13th century. The addition is Early English, and its carving is very elaborate and beautiful. The beautiful lady-chapel was begun by Bishop Hotham, and when the Norman tower erected by Abbot Simeon fell in 1321, the same bishop rebuilt it enlarged in the form of an octagon, and crowned it with a lofty lantern. This addition, as well as the lady-chapel, was designed by Alan of Walsingham. The total length of the cathedral from east to west is 525 feet, and the western tower is 220 feet high. The interior is exceedingly beautiful, and contains many interesting monuments. The cathedral has lately undergone extensive restoration under the direction of Sir G. G. Scott, R.A., which is still in progress, and has already cost more than £60,000. The church of the Holy Trinity, which is attached to the cathedral, was commenced in the reign of Edward II., and is one of the most perfect buildings of that age. St. Mary's church is also a handsome structure, partly in the Norman and partly in the Early English style of architecture. The population of the two parishes of Ely, including an extensive rural district, in 1871 was 8166.

Arms of Ely Bishopric.



Ground-plan of Ely Cathedral.

ELYSIUM, a name given by the Greeks to the abode of the righteous dead, who, in the words of Pindar, inherit there a tearless eternity (*Ol.*, ii. 120). In the *Odyssey*, iv. 563, this region, which answers to the Hindu Sutala, is spoken of as a plain at the end of the earth, where the fair-haired Rhadamanthys lives, and where the people are vexed by neither snow nor storm, heat nor cold, the air being always tempered by the zephyr wafted to them from the ocean. In the Hesiodic *Weeks and Days*, 166, the same description is given of the islands of the blessed, which yield three harvests yearly. These are near the Deep-eddying Ocean, but the sovereign who rules them is not Rhadamanthys, but Cronus. In Pindar, Rhadamanthys (whose name has by some been identified with the Egyptian Rhotamenti, or king of the under-world) sits by the side of his father Cronus and administers sound judgment. In later accounts this idea is developed into the tribunal of Minos, Rhadamanthys, and Æacus, before which all must appear in order to receive for their righteous or their evil lives the sentence which secures to them an entrance into Paradise or condemns them to be thrust down into Tartarus. Elsewhere Æacus is the gate-keeper of the under-world, near whom the hell-hound Kerberos (Cerberus) keeps watch. The images under which these abodes of the blessed are described point clearly to the phenomena of sunset, and reappear in the pictures drawn of the palace of Alkinoös (Alcinoüs). They reflect the spotless purity of a heaven lit up by the sun, which tinges with gold the cloud islands as they float on the deep blue sky. Here are the asphodel meadows, which none but the pure in heart, the truthful, and the generous can be suffered to tread; and thus an idea which at the outset had been purely physical, suggested the thoughts of trial, atonement, and purification.

See Preller, *Griechische Mythologie*, i. 636, 645, ii. 129; Brown, *Great Dionysiak Myth*, 185; Muir, *Sanskrit Texts*, part iv. p. 7.

ELYOT, Sir Thomas, one of the most learned Englishmen of the time of Henry VIII., was the son of a certain Sir Richard Elyot, usually said to be of Suffolk, but, according to a suggestion by C. H. Cooper in *Notes and Queries*, 1853, more probably of Wiltshire. If an identification proposed by Wood be correct, Sir Thomas studied at St. Mary's Hall, Oxford, and obtained the degree of bachelor of arts in 1518 and that of bachelor of civil law in 1524; but according to Parker and others he belonged to Jesus College, Cambridge, and his name begins to appear in the list of justices of assize for the Western Circuit about 1511. Be this as it may, he evidently received a university education, and, as he himself declares, soon became "desirous of reading many books, especially concerning humanity and moral philosophy." He continued to hold the office of clerk to the Western Assize till Wolsey persuaded him to exchange it for that of clerk of the king's council. The patent confirming the appointment is undated, but belongs to the year 1519. It grants him 40 marks a year and the usual summer and winter livery as enjoyed by Rob. Rydon, John Baldiswell, etc., and other profits as enjoyed by Ric. Eden or Rob. Ridon, on a conditional surrender of patent 21st Oct. 4. Henry VIII., granting the office to the said Rich. Eden. (Brewer, *Letters Foreign and Domestic of the Reign of Henry VIII.*, vol. iv.) According to Elyot's own account in a mournful letter addressed to Wolsey's great successor, he performed the duties of the clerkship for "six years and a half," but never received any of the emoluments, and never obtained a full recognition of his status (Henry Ellis, *Letters*, ii.). On his father's death he became involved in a lawsuit with his cousin Sir Wm. Tynderne about some property in Cambridgeshire; and though he ultimately gained his case, it proved a severe drain on his small estate. In 1532 he was sent on embassies to the papal and imperial courts, and while in Germany unfortunately received instructions to procure the arrest of Tyndale the Reformer. In this part of his mission he totally failed; and his efforts have since procured him the abuse of many a Protestant writer. His intimacy with Sir Thomas More appears to have awakened the suspicions of the king or his minister, for we find him writing to Cromwell that his friendship for the ill-fated scholar went no further than *usque ad aras*. He begs for a share in the confiscated property of the monasteries, and offers to give Cromwell the first year's revenue. Unless his letters are to be distrusted, he was for the greater part of his life in very poor circumstances, and, in spite of the rolling rhetoric with which in his prefaces he celebrates the magnanimity of his patrons, received little from them but promises and praise. He died in 1546, and was buried at Carleton, in Cambridgeshire. Among his contemporaries and his immediate successors Elyot enjoyed a high reputation as a scholar; and his future fame was secured by his Latin dictionary and his book called the *Governor*. The latter treats of the way in which a child ought to be trained who is afterwards expected to become a governor of men, and in so doing discusses such subjects as friendship, punishment, dancing, etc. The former, remarkable as the first English book of its kind, contains not only purely lexicographical matter, but little paragraphs on geographical, mythological, and historical proper names, and descriptions of natural objects, diseases, and the like. As a writer Sir Thomas was eminently didactic; his works have all a direct practical purpose, and he is not slow to assert the benefit that must accrue to the reader's character from their perusal.

The following is a list:—*The Boke named the Gouernour*, London, 1531, and frequently afterwards; reprinted in 1834, Newcastle, by A. T. Eliot; *The knowledge which maketh a wise man*, 1533; *Pasquine the playne*, 1535; Isocrates's *Doctrinal of Princes*, 1534; Pico de Mirandula's *Rules of a Christian Life*, 1534; *The Castell of Health, compiled out of the chief authours of Physick*, 1534; *Dictionarium*, 1538 (a copy in the Brit. Museum belonged to Cromwell, and has an autograph Latin letter from Elyot on the blank leaf at the beginning); *The Image of Governance, compiled of the actes and sentences notable of the most noble emperor Alexander Severus*, 1540 (translated, according to the author's fictitious account, for which he is bitterly attacked by Bayle, from the Greek of Encolpius, which had been lent him by a gentleman of Naples, called Pudericus, but called back before he had his translation quite complete); *The Bankette of Sapience*, 1542; *Preservative agaynste Death*, 1545; *Defence for good Women*, 1545. Roger Ascham mentions his *De rebus memorabilibus Angliæ;* and Webbe quotes from his translation of Horace's *Poetica*.

See Strype's *Ecclesiastical Memorials*, i., and appendix No. lxii.; *Archæologia*, xxiii., and Wright's *Suppression of Monasteries*, Camden Soc. 1843, both containing the begging letter to Cromwell; *Privy Purse Expenses of Princess Mary*, 82, 230; Wood's *Athenæ Oxonienses;* Ames, *sub nomine* Berthelet; Demaus, *Life of Tyndale*, 1871.

ELZEVIR, the name of a celebrated family of Dutch printers belonging to the 17th century. The original name was Elsevier, or Elzevier, and their French editions mostly retain this name; but in their Latin editions, which are the more numerous, the name is spelt Elzeverius, which was gradually corrupted into Elzevir. The family originally came from Louvaine, and there Louis, who first made the name Elzevir famous, was born in 1540. He learned the business of a bookbinder, and having been compelled in 1580, on account of his political opinions, to leave his native country, he established himself as bookbinder and bookseller in Leyden. His *Eutropius*, which appeared in 1592, was long regarded as the earliest Elzevir, but the first is now known to be *Drusii Ebraicarum quæstionum ac responsionum libri duo*, which was produced in 1583. In all he published about 150 works. His typographical mark was the arms of the United Provinces—an eagle on a cippus holding in its claws a sheaf of seven arrows, with the inscription *Concordia res parvæ crescunt*. He died February 4, 1617. Of his five sons, Matthieu, Louis, Gilles, Joost, and Bonaventure, who all adopted their father's profession, Bonaventure, who was born in 1583, is the most celebrated. He commenced business as a printer in 1608, and in 1626 took into partnership Abraham, a son of Matthieu, born at Leyden in 1592. Abraham died 14th August, 1652, and Bonaventure about a month afterwards. The fame of the Elzevir editions rests chiefly on the works issued by this firm. Their Greek and Hebrew impressions are considered inferior to those of the Aldos and the Estiennes, but their small editions in 12mo, 16mo, and 24mo, for elegance of design, neatness, clearness, and regularity of type, and beauty of paper, cannot be surpassed. Especially may be mentioned the *Novum Testamentum Græcum*, 1624, 1633; the *Psalterium Davidis*, 1635, 1653; *Virgilii Opera*, 1636, *Terentii Comediæ*, 1635; but the works which gave their press its chief celebrity are their collection of French authors on history and politics in 24mo, known under the name of the *Petites Republiques*, and their series of Latin, French, and Italian classics in small 12mo. Jean, son of Abraham, born in 1622, had since 1647 been in partnership with his father and uncle, and when they died Daniel, son of Bonaventure, born in 1626, joined him. Their partnership did not last more than two years, and after its dissolution Jean carried on the business alone till his death in 1661. In 1654 Daniel joined his cousin Louis (the third of that name and son of the second Louis), who was born in 1604, and had established a printing press at Amsterdam in 1638. From 1655 to 1666 they published a series of Latin classics in 8vo, *cum notis variorum; Cicero* in 4to; the *Etymologicon Linguæ Latinæ;* and a magnificent *Corpus Juris* in folio, 2 vols., 1663. Louis died in 1670, and Daniel in 1680. Besides Bonaventure, another son of Matthieu, Isaac, born in 1593, established a printing press at Leyden, where he carried on business from 1616 to 1625; but none of his editions attained much fame. The last representatives of the Elzevir printers were Peter, grandson of Joost, who from 1667 to 1672 was a bookseller at Utrecht, and printed seven or eight volumes of little consequence; and Abraham, son of the first Abraham, who from 1681 to 1712 was university printer at Leyden.

Many of the Elzevir editions bear no other typographical mark than simply the words *Apud Elzeverios*, or *Ex officina Elseveriana*, under the *rubrique* of the town. Isaac took as typographical mark the branch of a tree surrounded by a vine branch bearing clusters of fruit, and below it a man standing, with the motto *Non solus*. The third Louis adopted Minerva with an olive branch, and the motto *Ne extra oleas*. When the Elseviers did not wish to put their name to their works they generally marked them with a sphere, but of course the mere fact that a work printed in the 17th century bears this mark is no proof that it is theirs. The total number of works of all kinds which bear the name of the Elseviers is 1213, of which 968 are in Latin, 44 in Greek, 126 in French, 32 in Flemish, 22 in the Eastern languages, 11 in German, and 10 in Italian.

See "Notice de la collection d'auteurs latins, français, et italiens, imprimée de format petit en 12, par les Elsévier," in Brunet's *Manuel du Libraire* (Paris, 1820); Bérard's *Essai bibliographique sur les éditions des Elzévirs* (Paris, 1822); De Reume, *Recherches historiques, généalogiques, et bibliographiques sur les Elsévier* (Brussels, 1847); Paul Dupont, *Histoire de l'imprimerie*, in two vols. (Paris, 1854); Pieter, *Annales de l'imprimerie Elsevirienne* (2d ed., Ghent, 1858): Walther, *Les Elseveriennes de la bibliothèque impériale de St. Petersbourg* (St. Petersburg, 1864).

EMANUEL (Portuguese, MANOEL) I. (1469–1521), king of Portugal, surnamed the Happy, was the son of Duke Ferdinand of Viseu and cousin of John II. of Portugal, and was born May 3, 1469. The care of his early education was confided to a Sicilian named Cataldo, under whom he made rapid progress, especially in the classical languages. He succeeded to the throne on the death of John II., 27th October, 1495. In 1497 he married Donna Isabella, daughter of Ferdinand and Isabella of Castile. She died in 1498, and two years after her death he married her sister Donna Maria. As soon as he mounted the throne Emanuel devoted himself with great ardor to the maritime enterprises begun by his predecessor. He despatched Vasco da Gama to sail round the Cape of Good Hope in order to discover a new passage to India, and on his return he sent Pedro Alvarez de Cabral to complete his discoveries. Cabral discovered Brazil and the Moluccas, and established commercial relations with the Indian and African coasts. Through these expeditions and others under Albuquerque, the influence of Portugal was rendered predominant on the coasts of South Africa and the Indian archipelago, and an inexhaustible field for commerce and colonization was opened up to the Portuguese. Emanuel also entered into commercial relations with Persia, Ethiopia, and China. His whole foreign policy, with the exception of an attempt to conquer Morocco, was a brilliant success; and at the close of his reign Portugal had attained a degree of prosperity, both external and internal, until then unexampled in her history. He was also no less anxious for the individual welfare of his subjects than for the outward prosperity of his kingdom. He made personal visits to all his provinces to inquire into the administration of justice, and he is the author of a code of laws which bears his name. At certain stated hours he was accessible to any of his subjects without distinction who desired redress of grievances, or had any request of importance to make, and so great was his courtesy and patience in listening to their statements that when necessary he sacrificed to them hours that he usually devoted to enjoyment or repose. His persecutions of the Jews, cruel as they were, can scarcely be blamed when we remember the bigotry of his time and country; and it says much for his impartial administration of justice that he caused the ringleaders of a popular insurrection against that people to be executed with the usual marks of opprobrium. He died at Lisbon, December 13, 1521.

EMANUEL-BEN-SALOMON, a Hebrew poet of whose life the few facts that are known are gathered from allusions in his works. He was born at Rome about the middle of the 13th century, and spent the greater part of his life in that city. He seems also to have resided for a considerable period at Fermo. The precise date of his death, like that of his birth, is unknown. His collected poems, entitled *Mechabberoth*, were printed at Brescia in 1491 and at Constantinople in 1535. Both editions are exceedingly rare. The work contains about thirty different poems of various kinds, love songs, drinking songs, odes, madrigals, etc. The last is a descriptive poem, the subject being heaven and hell, and it was published separately at Prague in 1559 and at Frankfort in 1713. As a poet Emanuel is distinguished by the liveliness of his fancy and the finish of his versification. His choice of subjects, and his free method of treating them, led to his being proscribed by the stricter rabbis as a blasphemer. He has been called the Voltaire of the Hebrews, but with even less appropriateness than such far-fetched comparisons generally possess. Besides his poetical works, Emanuel wrote commentaries on several of the books of the Old Testament Scriptures, some of which exist only in manuscript. He was also the author of a work on Hebrew grammar and criticism.

EMBALMING (Greek, *βάλσαμον*, balsam; German, *einbalsamiren;* French, *embaumement*), the art of preparing dead bodies, chiefly by the use of medicaments, in order to preserve them from putrefaction and the attacks of insects. The ancient Egyptians carried the art to great perfection, and embalmed not only human beings, but cats, crocodiles, ichneumons, and other sacred animals. It has been suggested that the origin of embalming in Egypt is to be traced to a want of fuel for the purpose of cremation, to the inadvisability or at some times impossibility of burial in a soil annually disturbed by the inundation of the Nile, and to the necessity, for sanitary reasons, of preventing the decomposition of the bodies of the dead when placed in open sepulchres. As, however, the corpses of the embalmed must have constituted but a small proportion of the aggregate mass of animal matter daily to be disposed of, the above explanation is far from satisfactory; and it may be questioned whether embalming, together with the greater number of the Egyptian doctrines concerning a future life, may not have entirely originated in superstition or sentiment concerning the dead. According to Prescott, it was a belief in a resurrection of the body that led the ancient Peruvians to preserve the air-dried corpses of their dead with so much solicitude (see *Conquest of Peru*, bk. i. chap. iii.). Prichard (*Egyptian Mythology*, p. 200) holds it as probable that the views with which the Egyptians embalmed bodies were "akin to those which rendered the Greeks and Romans so anxious to perform the usual rites of sepulture to their departed warriors, namely, . . . that these solemnities expedited the journey of the soul to the appointed region, where it was to receive judgment for its former deeds, and to have its future doom fixed accordingly." It has been supposed by some that the discovery of the preservation of bodies interred in saline soils may have been the immediate origin of embalming in Egypt. In that country certain classes of the community were specially appointed for the practice of the art. Joseph, we are told in Gen. l. 2, "commanded his servants the physicians to embalm his father." Herodotus (ii. 86) gives an account of three of the methods of embalming followed by the Egyptians. The most expensive of these, which cost a talent of silver (£243, 15s.), was as follows. The brains were in part removed through the nostrils by means of a bent iron implement, and in part by the injection of drugs. The intestines having been drawn out through an incision in the left side, the abdomen was cleansed with palm-wine, and filled with myrrh, cassia, and other materials, and the opening was sewed up. This done, the body was steeped seventy days in a solution of litron or natron.[1] Diodorus (i. 91) relates that the cutter (*παρασχίστης*) appointed to make the incision in the flank for the removal of the intestines, as soon as he had performed his office, was pursued with stones and curses by those about him, it being held by the Egyptians a detestable thing to commit any violence or inflict a wound on the body. After the steeping, the body was washed, and handed over to the swathers, a peculiar class of the lowest order of priests, called by Plutarch *cholchytæ*, by whom it was bandaged in gummed cloth; it was then ready for the coffin. Mummies thus prepared were considered to represent Osiris. In another method of embalming, costing twenty-two minæ (about £90), the abdomen was injected with "cedar-tree pitch" (*κεδοία*), which, as it would seem from Pliny (*Nat. Hist.*, xvi. 21), was the liquid distillate of the pitch-pine. This is stated by Herodotus to have had a corrosive and solvent action on the viscera. After injection the body was steeped a certain number of days in natron; the contents of the abdomen were allowed to escape; and the process was then complete. The preparation of the bodies of the poorest consisted simply in placing them in natron for seventy days, after a previous rinsing of the abdomen with "syrmæa." The material principally used in the costlier modes of embalming appears to have been asphalt; wax was more rarely employed. In some cases embalming seems to have been effected by immersing the body in a bath of molten bitumen. Tanning also was resorted to. Occasionally the viscera, after treatment, were in part or wholly replaced in the body, together with wax figures of the four genii of Amenti. More commonly they were embalmed in a mixture of sand and asphalt, and buried in vases, or *canopi*, placed near the mummy, the abdomen being filled with chips and sawdust of cedar and a small quantity of natron. In one jar were placed the stomach and large intestine; in another, the small intestines; in a third, the lungs and heart; in a fourth, the gall-bladder and liver. Porphyry (*De Abstinentia*, iv. 10) mentions a custom of inclosing the intestines in a box, and consigning them to the Nile, after a prayer uttered by one of the embalmers, but his statement is regarded by Sir J. G. Wilkinson as unworthy of belief. The body of Nero's wife, Poppæa, contrary to the usage of the Romans, was not burnt, but, as customary among other nations with the bodies of potentates, was honored with embalmment (see Tacitus, *Annal.*, xvi. 6). The body of Alexander the Great is said to have been embalmed with honey (Statius, *Sylv.*, iii. 2, 117), and the same material was used to preserve the corpse of Agesipolis I. during its conveyance to Sparta for burial. Herodotus states (iii. 24) that the Ethiopians, in embalming, dried the body, rubbed it with gypsum (or chalk), and, having painted it, placed it in a block of some transparent substance. The Guanches, the aborigines of the Canaries, employed a mode of embalming similar to that of the Egyptians, filling the hollow caused by the removal of the viscera with salt and an absorbent vegetable powder (see Bory de Saint Vincent, *Essais sur les Iles Fortunées*, 1803, p. 495). Embalming was still in vogue among the Egyptians in the time of St. Augustine, who says that they termed mummies *gabbaræ* (*Serm.* 120, cap. 12). In modern times numerous methods of embalming have been practised. By William Hunter essential oils, alcohol, cinnabar, camphor, saltpetre, and pitch or rosin were employed, and the final desiccation of the body was effected by means of roasted gypsum placed in its coffin. Boudet embalmed with tan, salt, asphalt, and Peruvian bark, camphor, cinnamon and other aromatics, and corrosive sublimate. The last-mentioned drug, the chloride and sulphate of zinc, the acetate and sulphate of aluminium, and creasote and carbolic acid have all been recommended by various modern embalmers.

See MUMMY; Louis Penicher, *Traité des Embaumements*, Paris, 1669; S. Blancard, *Anatomia Reformata, et de Balsamatione nova methodus*, Lugd. Bat. 1695; Thomas Greenhill, *The Art of Embalming*, Lond. 1705; J. N. Marjolin, *Manuel d'Anatomie*, Paris, 1810; Pettigrew, *History of Mummies*, Lond. 1834; Gannal, *Traité d'Embaumements*, Paris, 1838; 2d ed. 1841; Magnus, *Das Einbalsamiren der Leichen*, Brunsw., 1839; Rawlinson's *Herodotus*, vol. ii. p. 141.

EMBANKMENT is an engineering term used to denote any large heap of materials collected together by artificial means. Embankments are constructed for carrying roads or railways across valleys. They are also employed for protecting land from the encroachments of river floods, and on a larger scale, in low-lying countries, as a defence against the inroads of the sea. Embankments are also the main features in almost all schemes of water-works, being used for impounding water for supply of towns or compensation to mills. See IRRIGATION and WATER-WORKS.

EMBER DAYS AND EMBER WEEKS, the four seasons set apart by the Western Church for special prayer and fasting, and the ordination of clergy, known in the mediæval church as *quatuor tempora*, or *jejunia quatuor temporum*. The Ember weeks are the complete weeks next following Holy Cross Day (September 14), St. Lucy's Day (December 13), the first Sunday in Lent, and Whitsun Day. The Wednesdays, Fridays, and Saturdays of these weeks are the Ember days distinctively, the following Sundays being the days of ordination. These dates are given in the following memorial distich with a frank indifference to quantity and metre—

---

[1] Neutral carbonate of sodium, Na_2Co_3, found at the natron lakes in the Libyan desert, and at El Hegs, in Upper Egypt.

> Vult Crux, Lucia, Cinis, Charismata dia
> Quod det vota pia quarta sequens feria.

The word *Ember* is of uncertain derivation. We may at once dismiss, as founded only on an accidental similarity of sound, that from the "embers" or ashes erroneously assumed to have been used at these seasons in token of humiliation. Other more probable derivations are from the Anglo-Saxon *ymb-ren*, a circuit or revolution (from *ymb*, around, and *rennen*, to run); or by process of agglutination and phonetic decay, from the Latin *quatuor tempora*. Those who advocate this latter derivation appeal to the analogous forms by which these seasons are designated in some of the Teutonic languages, *e.g.*—German, *quatember;* Dutch, *quatertemper;* Danish, *kvatember;* Swedish, *tamperdagar*. But the occurrence of the Anglo-Saxon compounds *ymbren-tid, ymbren-wucan, ymbren-faestan, ymbren-dagas*, for Ember tide, weeks, fasts, days, favors the former derivation, which is also confirmed by the use of the word *imbren* in the Acts of the council of Ænham, 1009 A.D. ("jejunia quatuor tempora quæ *imbren* vocant"). It corresponds also with Pope Leo the Great's definition, "jejunia ecclesiastica per totius anni circulum distributa."

The observance of the Ember days is confined to the Western Church, and had its origin as an ecclesiastical ordinance in Rome. They were probably at first merely the fasts preparatory to the three great festivals of Christmas, Easter, and Pentecost. A fourth was subsequently added, for the sake of symmetry, to make them correspond with the four seasons, and they became known as the *jejunium vernum, æstivum, autumnale*, and *hiemale*, so that, to quote Pope Leo's words, "the law of abstinence might apply to every season of the year." An earlier mention of these fasts, as four in number—the first known—is in the writings of Philastrius, bishop of Brescia, in the middle of the 4th century. He also connects them with the great Christian festivals (*De Hæres.*, 119). In Leo's time, 440-461 A.D., Wednesday, Friday, and Saturday were already the days of special observance. From Rome the Ember days gradually spread through the whole of Western Christendom. Uniformity of practice, however, in this particular was of somewhat slow growth. Neither in Gaul nor Spain do they seem to have been generally recognized much before the 8th century. Their introduction into Britain appears to have been earlier, dating from Augustine, 597 A.D., acting under the authority of Gregory the Great. The general period of the four fasts being roughly fixed, the precise date appears to have varied considerably, and in some cases to have lost its connection with the festivals altogether. The *Ordo Romanus* fixes the spring fast in the first week of March (then the first month); the summer fast in the second week of June; the autumnal fast in the third week of September; and the winter fast in the complete week next before Christmas eve. Other regulations prevailed in different countries, until the inconveniences arising from the want of uniformity led to the rule now observed being laid down under Pope Urban II. as the law of the church, in the councils of Placentia and Clermont, 1095 A.D.

The present rule which fixes the ordination of clergy in the Ember weeks cannot be traced further back than the time of Pope Gelasius, 492-496 A.D. In the early ages of the church ordinations took place at any season of the year whenever necessity required. Gelasius is stated by ritual writers to have been the first who limited them to these particular times, the special solemnity of the season being in all probability the cause of the selection. The rule once introduced commended itself to the mind of the church, and its observance spread. We find it laid down in the pontificate of Archbishop Egbert of York, 732-766 A.D., and referred to as a canonical rule in a capitulary of Charles the Great, and it was finally established as a law of the church in the pontificate of Gregory VII., c. 1085.

V.)

EMBEZZLEMENT, in English law, is a peculiar form of theft which is distinguished from the ordinary crime in two points:—(1) It is committed by a person who is in the position of clerk or servant to the owner of the property stolen; and (2) the property when stolen is in the possession of such clerk or servant. The definition of embezzlement as a special form of theft arose out of the difficulties caused by the legal doctrine that to constitute larceny the property must be taken out of the possession of the owner. Servants and others were thus able to steal with impunity goods intrusted to them by their masters. The statute 21 Henry VIII. c. 7 was passed to meet this case; and it enacted that it should be felony in servants to convert to their own use caskets, jewels, money, goods, or chattels delivered to them by their masters. "This Act," says Sir J. F. Stephen (*General View of the Criminal Law of England*), "assisted by certain subtleties according to which the possession of the servant was taken under particular circumstances to be the possession of the master, so that the servant by converting the goods to his own use took them out of his own possession *qua* servant (which was his master's possession) and put them into his own possession *qua* thief (which was a felony), was considered sufficient for practical purposes for more than 200 years." In 1799, a clerk who had converted to his own use a check paid across the counter to him by a customer of his master was held to be not guilty of felony; and in the same year the Act 39 Geo. III. c. 85 was passed, which, meeting the difficulty in such cases, enacted that if any clerk or servant, or any person employed as clerk or servant, should by virtue of such employment, receive or take into his possession any money, bonds, bills, etc., for or in the name or on account of his employers, and should fraudulently embezzle the same, every such offender should be deemed to have stolen the same. The same definition is substantially repeated in a Consolidation Act passed in 1827 (7 and 8 Geo. IV. c. 29). Numberless difficulties of interpretation arose under these Acts, *e.g.*, as to the meaning of "clerk or servant," as to the difference between theft and embezzlement, etc. The law now in force, or the Larceny Act, 24 and 25 Vict. c. 96, defines the offence thus (section 68):—"Whosoever being a clerk or servant, or being employed for the purpose or in the capacity of a clerk or servant, shall fraudulently embezzle any chattel, money, or valuable security which shall be delivered to or received or taken into possession by him for or in the name or on the account of his master or employer, or any part thereof, shall be deemed to have feloniously stolen the same from his master or employer, although such chattel, money, or security was not received into the possession of such master or employer otherwise than by the actual possession of his clerk, servant, or other person so employed, and being convicted thereof shall be liable, at the discretion of the court, to be kept in penal servitude for any time not exceeding fourteen years, and not less than three (now five) years." To constitute the offence thus described three things must concur:—(1) The offender must be a clerk or servant; (2) he must receive into his possession some chattel on behalf of his master; and (3) he must fraudulently embezzle the same. A clerk or servant has been defined to be a person bound either by an express contract of service or by conduct implying such a contract to obey the orders and submit to the control of his master in the transaction of the business which it is his duty as such clerk or servant to transact. (Stephen's *Digest of the Criminal Law*, Art. 309.) The Larceny Act also describes similar offences on the part of persons, not being clerks or servants, to which the name embezzlement is not uncommonly applied, *e.g.*, the fraudulent conversion by bankers, merchants, brokers, attorneys, or other agents, of money or securities or goods intrusted to them. This offence is a misdemeanor punishable by penal servitude for any term not exceeding seven nor less than five years. So also trustees fraudulently disposing of trust property, and directors of companies fraudulently appropriating the company's property or keeping fraudulent accounts, or wilfully destroying books or publishing fraudulent statements, are misdemeanants punishable in the same way.

EMBLEMENTS, in English law, means the growing crops which belong to the tenant of an estate of uncertain duration, which has unexpectedly determined without any fault of his own. "It is derived from the French *emblavence de bled* (corn sprung or put up above ground), and strictly signifies the growing crops of sown land; but the doctrine of emblements extends not only to corn sown, but to roots planted and other annual artificial profits" (Woodfall on

Landlord and Tenant). If the estate, although of uncertain duration, is determined by the tenant's own acts, the right to emblements does not arise. By 14 and 15 Vict. c. 25, a tenant at rack-rent, whose lease has determined by the death or cession of estate of a landlord entitled only for life, or for any other uncertain interest, shall, instead of emblements, be entitled to hold the lands until the expiration of the current year of his tenancy.

EMBOSSING is the art of producing raised portions or patterns on the surface of metal, leather, textile fabrics, cardboard, paper, and similar substances. Strictly the term is applicable only to raised impressions produced by means of engraved dies or plates brought forcibly to bear on the material to be embossed, by various means, according to the nature of the substance acted on. Thus raised patterns produced by carving, chiselling, casting, and chasing or hammering are excluded from the range of embossed work. Embossing supplies a convenient and expeditious medium for producing elegant ornamental effects in many distinct industries; and especially in its relations to paper and cardboard its applications are varied and important. Crests, monograms, addresses, etc., are embossed on paper and envelopes from dies (see Die Sinking) set in small hand-screw presses, a force or counter-die being prepared in leather faced with a coating of gutta-percha. The dies to be used for plain embossing are generally cut deeper than those intended to be used with colors. Color embossing is done in two ways—the first and ordinary kind that in which the ink is applied to the raised portion of the design. The color in this case is spread on the die with a brush, and the whole surface is carefully cleaned, leaving only ink in the depressed parts of the engraving. In the second variety—called cameo embossing—the color is applied to the flat parts of the design by means of a small printing roller, and the letters or design in relief are left uncolored. In embossing large ornamental designs, engraved plates or electrotypes therefrom are employed, the force or counterpart being composed of mill-board faced with gutta-percha. In working these, powerful screw-presses, in principle like coining or medal-striking presses, are employed. Embossing also is most extensively practised for ornamental purposes in the art of bookbinding. The blocked ornaments on cloth covers for books, and the blocking or imitation tooling on the cheaper kinds of leather work, are effected by means of powerful embossing or arming presses. (See Bookbinding.) For impressing embossed patterns on wall papers, textiles of various kinds, and felt, cylinders of copper, engraved with the patterns to be raised, are employed, and these are mounted in calender frames, in which they press against rollers having a yielding surface, or so constructed that depressions in the engraved cylinders fit into corresponding elevations in those against which they press. The operations of embossing and color printing are also sometimes effected together in a modification of the ordinary cylinder printing machine used in calico-printing, in which it is only necessary to introduce suitably engraved cylinders. For many purposes the embossing rollers must be maintained at a high temperature while in operation; and they are heated either by steam, by gas jets, or by the introduction of red-hot irons within them. The stamped or struck ornaments in sheet metal, used especially in connection with the brass and Britannia metal trades, are obtained by a process of embossing—hard steel dies with forces or counter-parts of soft metal being used in their production (see Brass). A kind of embossed ornament is formed on the surface of soft wood by first compressing and consequently sinking the parts intended to be embossed, then planing the whole surface level, after which, when the wood is placed in water, the previously depressed portion swells up and rises to its original level. Thus an embossed pattern is produced which may be subsequently sharpened and finished by the ordinary process of carving.

EMBROIDERY[1] is the art of working with the needle flowers, fruits, human and animal forms upon wool, silk, linen, or other woven texture. That it is of the greatest antiquity we have the testimony of Moses and Homer, and it takes precedence of painting, as the earliest method of representing figures and ornaments was by needle-work traced upon canvas. From the earliest times it served to decorate the sacerdotal vestments and other objects applied to ecclesiastical use, and queens deemed it an honor to occupy their leisure hours in delineating with the needle the achievements of their heroes. The Jews are supposed to have derived their skill in needle-work from the Egyptians, with whom the art of embroidery was general; they produced figured cloths by the needle and the loom, and practised the art of introducing gold thread or wire into their work. Amasis, king of Egypt, sent to the Minerva of Lindus a linen corslet with figures interwoven and embroidered with gold and wool; and, to judge from a passage in Ezekiel, they even embroidered the sails of their galleys which they exported to Tyre: "Fine linen with broidered work from Egypt was that which thou spreadest forth to be thy sail." Embroidery and tapestry are often confounded; the distinction should be clearly understood. Embroidery is worked upon a woven texture having both warp and woof, whereas tapestry is wrought in a loom upon a warp stretched along its frame, but has no warp thrown across by the shuttle; the weft is done with short threads variously colored and put in by a kind of needle.

The book of Exodus describes how the curtains of the tabernacle were embroidered by hand, and the garments of Aaron and his sons were wrought in needle-work. Aholiab, the chief embroiderer, is specially appointed to assist in the work of decoration. In celebrating the triumph of Sisera, his mother is made to say that he has a "prey of divers colors of needle-work on both sides," evidently meaning that the stuff was wrought on both sides alike, a style of embroidery exhibiting a degree of patience and skill only practised by the nations of the East.

Homer makes constant allusion to embroidery. Penelope (to say nothing for her immortal web) throws over Ulysses on his departure for Troy an embroidered garment of gold on which she had depicted incidents of the chase. Helen is described as sitting apart, engaged in working a gorgeous suit upon which she had portrayed the wars of Troy; and Andromache was embroidering flowers of various hues upon a purple cloth when the cries of the people without informed her of the tragic end of Hector. In Greece the art was held in the greatest honor, and its invention ascribed to Minerva, and prompt was her punishment of the luckless Arachne for daring to doubt her supremacy in the art. The maidens who took part in the procession of the Panathenia embroidered the veil or peplum, upon which the deeds of the goddess were worked in embroidery and gold.

Phrygia became celebrated for the beauty of its needle-work. The "toga picta" ornamented with Phrygian embroidery was worn by the Roman generals at their triumphs, and by their consuls when they celebrated the games—hence embroidery itself in Latin is styled "Phrygian," and the Romans knew it under no other name.

Babylon was no less renowned for its embroideries, and maintained its reputation up to the first century of the Christian era. Josephus tells us that the veils given by Herod for the temple were of Babylonian workmanship,—the women excelling, says Apollonius, in executing designs of varied colors. The Sidonian women brought by Paris to Troy embroidered veils of such rich embroidery that Hecuba deemed them worthy of being presented as an offering to Minerva; and Lucan speaks with enthusiasm of the magnificent Sidonian veil worn by Cleopatra at the feast she gave Cæsar after the death of Pompey. The embroidered robe of Servius Tullius was ornamented all over with the image of the goddess Fortune, to whom he ascribed his success, and to whom he built several temples. Tarquin the elder first appeared at Rome in a robe embroidered all over with gold, and Cicero describes Damocles as reclining on his bed with a coverlet of magnificent embroidery.

Passing to the first ages of the Christian era, we find the pontifical ornaments, the tissues that decorated the altars, and the curtains of the churches all worked with the holy images; and in the 5th century the art of weaving stuffs and enriching them with embroidery was carried to the highest degree of perfection. The whole history of the church was embroidered on the toga of a Christian senator; and Anastasius, who has left a description of ornaments of this kind given by popes and emperors to the churches from the 4th to the 9th century, has even recorded the subjects of these embroideries, which are executed in gold and silver thread upon silk stuffs of the most brilliant colors, producing a wonderful effect. "Opus plumarium" was then the general term for embroidery, and so given because stitches were laid down lengthwise and so put together that they seemed to overlap one another like the feathers in the plumage of a bird. Not inaptly, therefore, was this style called feather-stitch, in contradistinction to cross-stitch. Pope Paschal (5th century), a great admirer of needlework, made many splendid donations to the church. On one of his vestments were portrayed the Wise Virgins, miraculously worked; on another a peacock, in all the gorgeous and changing colors of its plumage, on an amber ground.

---

[1] French *bord, bordure;* Anglo-Saxon, *bord*—the edge or margin of anything, because embroidery was chiefly exercised upon the edge or border of vestments.

In mediæval times, spinning and embroidery were the occupation of women of all ranks, from the palace to the cloister, and a sharp rivalry existed in the production of sacerdotal vestments and ornaments. So early as the 6th century, St. Césaire, bishop of Arles, forbade the nuns under his rule from embroidering robes adorned with paintings, flowers, and precious stones. This prohibition, however, was not of a general character. Near Ely, an Anglo-Saxon lady brought together a number of girls who produced admirable embroidery for the benefit of the monastery; and in the 7th century, St. Eustadiole, abbess of Bourges, made sacred vestments and decorated the altar with works by herself and her community. A century later, two sisters, abbesses of Valentina, in Belgium, became famous for their excellence in all feminine pursuits, and imposed embroidery-work upon the inmates of their convent as a protection from idleness, the most dangerous of all evils.

At the beginning of the 9th century, ladies of rank are to be found engaged in embroidery. St. Viborade, living at St. Gall, adorned beautiful coverings for the sacred books of that monastery, it being then the custom to wrap in silk and carry on a linen cloth the Gospels used for the offices of the church; and the same abbey received from Hadwiga, daughter of Henry duke of Swabia, chasubles and ornaments embroidered by the hand of that princess. Judith of Bavaria, mother of Charles the Bald, was also a skilful embroideress. When Harold, king of Denmark, came to be baptized at Ingelheim with all his family, the empress Judith, who stood sponsor for the queen, presented her with a robe enriched by herself with gold and precious stones. In the 10th century, Queen Adhelaïs, wife of Hugh Capet, presented to the church of St. Martin at Tours, and another to the abbey of St. Denis, two chasubles of different designs, but of wonderful workmanship.

Long before the Conquest English ladies were much skilled with the needle. The beautiful "opus Anglicum" was produced under the Anglo-Saxons, and so highly was it valued that we find (800) Deubart, bishop of Durham, granting the lease of a farm of 200 acres for life to the embroideress Eanswitha for the charge of scouring, repairing, and renewing the embroidered vestments of the priests. In the 7th century, St. Ethelreda, queen and first abbess of Ely, presented to St. Cuthbert a stole and maniple marvellously embroidered and embellished with gold and precious stones. The four daughters of Edward the Elder are all praised for their needles' skill; and in the 10th century, Ælfleda, a high-born Saxon lady, gave to the church at Ely a curtain on which she had wrought in needle-work the deeds of daring of her husband Brithnoth, who was slain by the Danes. Later on, Emma, wife of Canute, enriched the same minster with costly stuffs, of which one at least had been embroidered all over with orfrays by the queen herself, and embellished with gold and gems disposed with such art and profusion as could not be matched at that time in all England.

The excellence of the English work was maintained as time went on, a proof of which is found in an anecdote related by Matthew of Paris:—"About this time" (1246), he tells us, "the Lord Pope (Innocent IV.), having observed that the ecclesiastical ornaments of some Englishmen, such as choristers' copes and mitres, were embroidered in gold thread after a very desirable fashion, asked where these works were made, and received in answer, in England. 'Then,' said the Pope, 'England is surely a garden of delights for us. It is truly a never-failing spring, and there, where many things abound, much may be extorted.' Accordingly, the same Lord Pope sent sacred and sealed briefs to nearly all the abbots of the Cistercian order established in England, requesting them to have forthwith forwarded to him those embroideries in gold, which he preferred to all others, and with which he wished to adorn his chasuble and choral cope, as if these objects cost them nothing." But it may be asked, what is the "opus Anglicum"? Happily in the Syon Monastery Cope, preserved in the South Kensington Museum, there is an invaluable specimen of English needlework of the 13th century. We find that the whole of the face is worked in chain-stitch (modern tambour or crochet) in circular lines, the relief being given by hollows sunk by means of hot irons. The general practice was to work the draperies in feather-stitch (opus plumarium).

The old English "opus consuetum" or cut-work, the "appliqué" or "en rapport" of the French, and "Lavori di commesso" of the Italians, consists of pieces cut and shaped out of silk or other material and sewed upon the grounding.

In the 11th or probably early in the 12th century was executed the valuable specimen preserved to us, the so-called tapestry of Bayeux, ascribed by early tradition to no less a lady than Queen Matilda, and representing the various episodes of the conquest of England by William of Normandy. It is not tapestry, but an embroidery-work in crewels in "long-stitch" of various colors, on a linen cloth 19 inches wide by 226 yards long. Probabilities forbid us from believing that Matilda and her waiting maids ever did a stitch on this canvas, which, crowded as it is with fighting men, some on foot, some on horseback, must have taken much time and busied many fingers to execute; nor is it likely that Matilda would have chosen coarse linen and common worsted as the materials with which to celebrate her husband's achievements. More likely, this curious work was done in London at the cost of those natives of Normandy on whom William had bestowed lands in England, and was sent by them as an offering to the cathedral of their native place. Whether it be due to the queen or not, the monument is no less interesting to history, as furnishing a crowd of details in illustration of arms and customs not to be met with elsewhere.

The art of pictorial needle-work had become universally spread. The inventory of the Holy See (1295) mentions the embroideries of Florence, Milan, Lucca, France, England, Germany, and Spain. The Paris embroiderers had formed themselves into a guild; and throughout the Middle Ages down to the 16th century, embroidery was an art, a serious branch of painting. The needle, like the brush of the painter, moved over the tissue, leaving behind its colored threads, and producing a painting soft in tone and ingenious in execution. At Verona, an artist took twenty-six years to execute in needle-work the life of St. John, after the designs of Pollaniolo, as an offering to that church at Florence. Catharine de' Medici, herself a distinguished needle-woman, brought over in her train from Florence the designer for embroidery, Frederick Vinciolo; and under her sons, so overloaded was dress with ornament as to be described by contemporaries as "stiff" with embroidery. These were indeed great days for needle-work in our own land. Women as well as men pursued the art as a trade, and the public records show to what an extent it was carried on; while great ladies wrought in their castles surrounded by their maidens. Embroidery was then their chief pleasure, and their most serious occupation. Shut out from the business of life, they had ample leisure to cultivate their taste, and ample means of gratifying it. The church was very rich in precious stuffs and embroideries, velvet, cut-work (appliqué) or cloth of gold; and for domestic decoration they were equally prized. Many of our great show-houses are perfect storehouses of embroidery. The countess of Shrewsbury, for instance, better known as Bess of Hardwick, the great needle-woman of the day, with all the business and cares of children, hospitals, and charities, yet found time to embroider furniture for her palaces, and her sampler patterns hang to this day on her walls; and there also are the bedhangings of Scotland's queen, who beguiled her weary hours by work at her needle. Hatfield, Penshurst, Knole, are all filled with similar reminiscences of royal and noble ladies. Charles I. used to send from his prison locks of his own hair to the gentry favorable to his cause, that the ladies of their household, when embroidering the royal portraiture in colored silks, might be able to work the head with the hair of the sovereign himself.

In France this time was a glorious period for needle-work. Not only was the fashion continued, as in England, of producing figures and portraits, but a fresh development was given to floral and arabesque ornament. Flowers in the grandiose style, wrought with arabesques of gold and silver, among which sported birds and insects, were the characteristic designs of the period; and Gaston duke of Orleans established hothouses and botanical gardens, which he filled with rare exotics, to supply the needle with new forms and richer tints. The crown manufacturers adorned the rich brocades of Tours, watered silks, and cloths of silver with patterns furnished by Charles Le Brun for the portières and curtains to the rooms he had designed. Hangings, furniture, costumes, equipages—embroidery invaded all. The throne of Louis XV., used for the reception of the Knights of the Holy Ghost, alone cost 300,000 livres; nor was the embroidery of the state coaches of Marie Antoinette less costly.

The history of embroidery having been carried to the end of the 18th century, a few observations remain on its state in the present day, when every country furnishes its works of the needle, from the gorgeous productions in gold and silver of the East to the humble porcupine quill and mohair embroidery of the Canadian Indian.

In an industrial point of view, the art may be ranged into two classes. First, there is white embroidery, applied to dress and furniture, upon cloth, muslin, or tulle, in which France and Switzerland hold the first place, and then Scotland and Saxony. The second class comprises works in silk, gold, and silver, the last two more especially dedicated to church ornaments and military costume. From the East we derive the most elaborate specimens of embroidery as applied to dress and furniture; for while in the West these are chiefly used for the church and costume, in the East every article of domestic use is covered with embroideries in silver and gold. The Chinese embroider the imperial dragon upon their robes of crimson satin; nor are the Japanese works less gorgeous or in less perfect taste. The Persians, in the 17th century, sent to Europe rich embroidered coverlets for the state beds of the period. They work extensively in chain-stitch. A supplementary division may be made of the so-called Berlin work, executed in wool and silk upon canvas, in cross-stitch, or point de marque, as it was formerly called, as being the stitch used for marking.

EMBRUN (the ancient *Ebrodunum*), a fortified town of France, capital of the arrondissement of the same name, in the department of Hautes-Alpes, is situated on a steep rock near the right bank of the Durance, 25 miles east of Gap. It has woollen and linen manufactures. Its principal buildings are the cathedral, said to have been founded in the time of Charlemagne, a handsome Gothic structure, surmounted with a lofty tower; the archiepiscopal palace; the ancient college of the Jesuits, now converted into a prison: and the ancient convent of the Capuchins. Embrun was an important military station in the time of the Romans. It was the seat of a bishop in the time of Constantine, and from the 9th century till the Revolution it ranked as an archbishopric. It has been sacked successively by the Vandals, the Huns, the Lombards, the Saxons, and the Saracens; and in the reign of Louis XIV. it was bombarded and taken by the duke of Savoy. The population in 1872 was 3075.

EMBRYOLOGY is a branch of biological inquiry comprising the history of the young of man and animals, and it may be also of plants. The term is derived from the Greek ἔμβρυον, signifying a growing part or thing, and has been somewhat vaguely applied to the product of generation of any plant or animal which is in process of formation. Among the higher animals, and especially in the human species, the Latin word *fœtus* has sometimes been employed in the same signification as embryo, but it is more generally held to denote a more advanced stage of formation, while the term embryo is applied to the earlier condition of the product of conception before it has assumed the characteristic form and structure of the parent.

In all animals, with the exception of the Protozoa, the new being, deriving its origin from a definite organized structure termed the ovum or egg, passes during the progress of its formation and growth from a simpler to a more complex form and organic structure by a series of consecutive changes which come under the general denomination of development. The consideration of these changes, which is mainly an anatomical subject, being partly morphological as affecting the larger and more obvious organic form, and partly histological as belonging to the minute or textural structure, constitutes by far the greater part of the science of embryology, but the latter word may also include the history of all other living phenomena manifested by the young animal in the progress of its growth to maturity.

The formative process through which the embryo passes is necessarily of very different degrees of complexity, according to the more simple or complex organization of the adult animal to which it belongs. But it presents throughout the whole range of animals certain general features of similarity dependent on the fundamental resemblance of the organized elements from which all animals derive their origin.

A minute mass of protoplasm constitutes not only the simplest, but also the invariable, form presented by the germinal part of the ovum or egg, and in all animals, except the Protozoa, in which the nature of the germ is still doubtful, it takes at first the form of an organized cell, or it is a definite spherical and nucleated mass of protoplasm. It is therefore a germ-cell.

In all ova, the first stage of the formative process, following upon fecundation of the germ, consists in the multiplication of the egg or germ-cell by a process of the nature of fissiparous division, so that when this division has proceeded some length, it results in the production of a mass or congeries of organized cells descended from that which formed the primitive germ, and containing in combination the molecular elements of the materials contributed by the male and female parents to the formation of the fertilized germ. This is the mulberry stage, or *morula*, of Haeckel. In a more advanced stage among the higher animals, the cells of this mass assume more or less of a laminar arrangement, constituting the *blastoderm* or germinal membrane of Pander and succeeding authors; and in the first and lowest forms of this structure two layers are distinguished, corresponding to the outer and inner cellular laminæ of which the earliest form of the embryo consists in the higher, and the whole of the body in the lower, forms of animals. These layers are the *ectoderm* and *endoderm* of the embryologist and comparative anatomist (Huxley and Allman).

In the lowest animals little if any further differentiation of the germinal structures ensues; but in animals higher in the scale there arises a third or intermediate layer, the *mesoderm*, which takes an important part along with the other two layers in the formation of the animal organism. The cellular blastoderm, therefore, is already the embryo of the lowest animals; while in the higher that term could scarcely with propriety be applied to the product of development in the egg until some of the characteristic lineaments, however, rudimentary, of the new animal are apparent.

But in the whole of this process of embryonic development, whether it be of the simplest or of the most complex kind, it is to be observed that it is solely by the multiplication and differentiation of cells which have descended more or less directly from the original germ-cell that the organizing process is effected. It follows from this that the processes of organic growth or embryonic development present a textural or histological uniformity to a remarkable degree throughout the whole zoological series. There is also a very striking similarity in the morphological phenomena of development within large groups of animals. Our knowledge, indeed, of the mode of formation of the young in all the varied forms of animal organization is still too limited to admit of our affirming that a uniform and progressive morphological type pervades the whole animal kingdom; but already many ascertained facts point strongly to such a conclusion, and the more our knowledge of the process of development in individual animals (*ontogeny*) advances, the greater resemblance do we recognize in the formative processes; so that it becomes more and more probable that the morphological development of any of the higher animals includes, or as it were repeats within certain limits, the various steps of the process which belong to the inferior grades of the animal kingdom. Hence we are led to the further conclusion that there is an essential correspondence between the individual development or ontogeny of the higher animals and the progressive advance of the organization in the whole animal series.

If, further, we adopt the Darwinian view of the evolution of animal life and organization by descent of one species of animals from others preceding it, we shall see that the embryological history of any animal is at the same time the history of its relation to other animals and of its phylogenetic development or gradual derivation as a species from more simple progenitors in the lapse of time. It is obvious, therefore, that we must look to the future progress of embryology as well as of palæontology for a large portion of the facts upon which the confirmation of the modern theory of evolution will rest.

From what has been said it will be apparent that it would be impossible within the limits of one article, to trace even in the briefest possible manner the phenomena of embryological development in all different animals. But special descriptions, so far as required, will find their appropriate places under the divisions of animals to which they respectively belong; and as there are some considerations relating to embryology which require to be stated besides the history of development, it has been deemed advisable to bring the more important facts of development of the embryo into connection with those relating to reproduction in general under the heading GENERATION, to which article, therefore, the reader is referred. In the present article, accordingly, we shall do no more than trace shortly the steps by which the modern science of Embryology has originated and has assumed the important position which it now occupies among the biological sciences.

In its scientific and systematic form embryology may be considered as having only taken birth within the present century, although the germ from which it sprung was already formed nearly half a century earlier. The ancients, it is true, as we see by the writings of Aristotle and Galen, pursued the subject with interest, and the indefatigable Grecian naturalist and philosopher had even made continued series of observations on the progressive stages of development in the incubated egg, and on the reproduction of various animals; but although, after the revival of learning, various anatomists and physiologists from time to time made contributions to the knowledge of the fœtal structure in its larger organs, yet from the minuteness of the observations required for embryological research, it was not till the microscope came into use for the investigation of organic structure that any intimate knowledge was attained of the nature of organogenesis. It is not to be wondered at, therefore, that during a long period, in this as in other branches of physical inquiry, vague speculations took the place of direct observation and more solid information. This is apparent in most of the works treating of generation during the 16th and part of the 17th centuries.[1]

Harvey was the first to give, in the middle of the latter century, a new life and direction to investigation of this subject, by his discovery of the connection between the cicatricula of the yolk and the rudiments of the chick, and by his faithful description of the successive stages of development as observed in the incubated egg, as well as of the progress of gestation in some Mammalia. He had also the merit of fixing the attention of physiologists upon general laws of development as deduced from actual observation of the phenomena, by the enunciation of two important propositions, viz.—(1) that all animals are produced out of ova, and (2) that the organs of the embryo arise by new formation, or *epigenesis*, and not by mere enlargement out of a pre-existing invisible condition (*Exercitationes de Generatione Animalium*, Amstelodami, 1651, and in English by G. Ent, 1853, London). Harvey's observations, however, were aided only by the use of magnifying glasses (perspecillæ), probably of no great power, and he saw nothing of the earliest appearances of the embryo in the first thirty-six hours, and believed the blood and the heart to be the parts first formed.

The influence of the work of Harvey, and of the successful application of the microscope to embryological investigation, was soon afterwards apparent in the admirable researches of Malpighi of Bologna, as evinced by his communications to the Royal Society of London in 1672, "De ovo incubato," and "De formatione pulli," and more especially in his delineations of some of the earlier phenomena of development, in which, as in many other parts of minute anatomy, he partially or wholly anticipated discoveries, the full development of which has only been accomplished in the present century. Malpighi traced the origin of the embryo almost to its very commencement in the formation of the cerebro-spinal groove within the cicatricula, which he removed from the opaque mass of the yolk; and he only erred in supposing the embryonal rudiments to have pre-existed as such in the egg, in consequence, apparently, of his having employed for observation, in very warm weather, eggs which, though he believed them to be unincubated, had in reality undergone some of the earlier developmental changes.

The works of Walter Needham (1667), Regner de Graaf (1673), Swammerdam (1685), Vallisneri (1689)—following upon those of Harvey—all contain important contributions to the knowledge of our subject, as tending to show the similarity in the mode of production from ova in a variety of animals with that previously best known in birds. The observations more especially of De Graaf, Nicolas Steno, and J. van Horne gave much greater precision to the knowledge of the connection between the origin of the ovum of quadrupeds and the vesicles of the ovary now termed Graafian, which De Graaf showed always burst and discharged their contents on the occurrence of pregnancy.

These observations bring us to the period of Boerhaave and Albinus in the earlier part of the 18th century, and in the succeeding years to that of Haller, whose vast erudition and varied and accurate original observations threw light upon the entire process of reproduction in animals, and brought its history into a more systematic and intelligible form. A considerable part of the seventh and the whole of the eighth volumes of Haller's great work, the *Elementa Physiologiæ*, published at successive times from 1757 to 1766, are occupied with the general view of the function of generation, while his special contributions to embryology are contained in his *Deux Mémoires sur la formation du Cœur dans le Poulet*, and *Deux Mémoires sur la formation des Os*, both published at Lausanne in 1758, and republished in an extended and altered form, together with his "Observations on the early condition of the Embryo in Quadrupeds," made along with Kühlemann, in the *Opera Minora* (1762–68). Though originally educated as a believer in the doctrine of "preformation" by his teacher Boerhaave, Haller was soon led to abandon that view in favor of "epigenesis" or new formation, as may be seen in various parts of his works published before the middle of the century; see especially a long note explanatory of the grounds of his change of opinion in his edition of Boerhaave's *Prælectiones Academicæ*, vol. v. part 2, p. 497 (1744), and his *Primæ Lineæ Physiologiæ* (1747). But some years later, and after having been engaged in observing the phenomena of development in the incubated egg, he again changed his views, and during the remainder of his life was a keen opponent of the system of epigenesis and a defender and exponent of the theory of "evolution," as it was then named—a theory very different from that now bearing the name, and which implied belief in the pre-existence of the organs of the embryo in the germ, according to the theory of encasement (emboitement) or inclusion supported by Leibnitz and Bonnet. (See the interesting work of Bonnet, *Considérations sur les Corps Organisés*, Amsterdam, 1762, for an account of his own views and those of Haller.) The reader is also referred to the article EVOLUTION in the present volume, for a further history of the change which has taken place in the use of the term in more recent times.

It was reserved for Caspar Frederick Wolff (1733–1794), a German by birth, but naturalized afterwards in Russia, to bring forward observations which, though almost entirely neglected for a long time after their publication, and in some measure discredited under the influence of Haller's authority, were sixty years later acknowledged to have established the theory of epigenesis upon the secure basis of ascertained facts, and to have laid the first foundation of the morphological science of embryology. Wolff's work, entitled *Theoria Generationis,* first published as an inaugural Dissertation at Berlin in 1759, was republished with additions in German at Berlin in 1764, and again in Latin at Halle in 1774. Wolff also wrote a "Memoir on the Development of the Intestine" in *Nov. Comment. Acad. Petropol.*, 1768 and 1769. But it was not till the latter work was translated into German by J. F. Meckel, and appeared in his *Archiv* for 1812, that Wolff's peculiar merits as the founder of modern embryology came to be known or fully appreciated.

---

[1] It may be proper to mention, as authors of this period who made special researches on the development of the embryo—(1) Volcher Coiter of Groningen, who, along with Aldrovandus of Bologna, made a series of observations on the formation of the chick, day by day, in the incubated egg, which were described in a work published in 1573, and (2) Hieronymus Fabricius (ab Aquapendente), who, in his work *De Formato Fœtu*, first published at Padua in 1600, gave an interesting account, illustrated by many fine engravings, of uterogestation and the fœtus of a number of quadrupeds and other animals, and in a posthumous work entitled *De formationi ovi et pulli*, edited by J. Prévost, and published at Padua in 1621, described and illustrated by engravings the daily changes of the egg in incubation. It is enough, however, to say that Fabricius was entirely ignorant of the earlier phenomena of development which occur in the first two or three days, and even of the source of the embryonic rudiments, which he conceived to spring, not from the yolk or true ovum, but from the chalazæ or twisted deepest part of the white. The cicatricula he looked upon as merely the vestige of the pedicle by which the yolk had previously been attached to the ovary.

The special novelty of Wolff's discoveries consisted mainly in this, that he showed that the germinal part of the bird's egg forms a layer of united granules or organized particles (cells of the modern histologist), presenting at first no semblance of the form or structure of the future embryo, but gradually converted by various morphological changes in the formative material, which are all capable of being traced by observation, into the several rudimentary organs and systems of the embyro. The earlier form of the embyro he delineated with accuracy; the actual mode of formation he traced in more than one organ, as for example in the alimentary canal, and he was the discoverer of several new and important embryological facts, as in the instance of the primordial kidneys, which have thus been named the Wolffian bodies. Wolff further showed that the growing parts of plants owe their origin to organized particles or cells, so that he was led to the great generalization that the processes of embryonic formation and of adult growth and nutrition are all of a like nature in both plants and animals. No advance, however, was made upon the basis of Wolff's discoveries till the year 1817, when the researches of Pander on the development of the chick gave a fuller and more exact view of the phenomena less clearly indicated by Wolff, and laid down with greater precision a plan of the formation of parts in the embryo of birds, which may be regarded as the foundation of the views of all subsequent embryologists.

But although the minuter investigation of the nature and true theory of the process of embryonic development was thus held in abeyance for more than half a century, the interval was not unproductive of observations having an important bearing on the knowledge of the anatomy of the fœtus and the function of reproduction. The great work of William Hunter on the human gravid uterus, containing unequalled pictorial illustrations of its subject from the pencil of Rymsdyk and other artists, was published in 1775;[1] and during a large part of the same period numerous communications to the *Memoirs* of the Royal Society testified to the activity and genius of his brother, John Hunter, in the investigation of various parts of comparative embryology. But it is mainly in his rich museum, and in the manuscripts and drawings which he left, and which have been in part described and published in the catalogue of his wonderful collection, that we obtain any adequate idea of the unexampled industry and wide scope of research of that great anatomist and physiologist.

As belonging to a somewhat later period, but still before the time when the more strict investigation of embryological phenomena was resumed by Pander, there fall to be noticed, as indicative of the rapid progress that was making, the experiments of Spallanzani, 1789; the researches of Autenrieth, 1797, and of Soemmering, 1799, on the human fœtus; the observations of Senff on the formation of the skeleton, 1801; those of Oken and Kieser on the intestine and other organs, 1806; Oken's remarkable work on the bones of the head, 1807 (with the views promulgated in which Goethe's name is also intimately connected); J. F. Meckel's numerous and valuable contributions to embryology and comparative anatomy, extending over a long series of years; and Tiedemann's classical work on the development of the brain, 1816.

Christian Pander's observations were made at the instance and under the immediate supervision of Prof. Döllinger at Würzburg, and we learn from Von Baer's autobiography that he, being an early friend of Panders, and knowing his qualifications for the task, had pointed him out to Döllinger as well fitted to carry out the investigation of development which that professor was desirous of having accomplished. Pander's inaugural dissertation was entitled *Historia metamorphoseos quam ovum incubatum prioribus quinque diebus subit,* Virceburgi, 1817; and it was also published in German under the title of *Beiträge zur Entwickelungsgeschichte des Hühnchens im Eie,* Würzburg, 1817. The beautiful plates illustrating the latter work were executed by the elder D'Alton, well known for his skill in scientific observation, delineation, and engraving.

Pander observed the blastoderm or germinal membrane of the fowl's egg to acquire three layers of organized substance in the earlier period of incubation. These he named respectively the serous or outer, the vascular or middle, and the mucous or inner layers; and he traced with great skill and care the origin of the principal rudimentary organs and systems from different ones of these layers, pointing out shortly, but much more distinctly than Wolff had done, the actual nature of the changes occurring in the process of development.

Carl Ernest von Baer, the greatest of modern embryologists, was, as already remarked, the early friend of Pander, and, at the time when the latter was engaged in his researches at Würzburg, was associated with Döllinger as prosector, and engaged with him in the study of comparative anatomy. He witnessed, therefore, though he did not actually take part in, Pander's researches; and the latter having afterwards abandoned the inquiry, Von Baer took it up for himself in the year 1819, when he had obtained an appointment in the university of Königsberg, where he was the colleague of Burdach and Rathke, both of whom were able coadjutors in the investigation of the subject of his choice. (See V. Baer's interesting autobiography, published on his retirement from St. Petersburg to Dorpat in 1864.)[2]

Von Baer's observations were carried on at various times from 1819 to 1826 and 1827, when he published the first results in a description of the development of the chick in the first edition of Burdach's *Physiology.*

It was at this time that Von Baer made the important discovery of the ovarian ovum of mammals and of man, totally unknown before his time, and was thus able to prove as matter of exact observation what had only been surmised previously, viz., the entire similarity in the mode of origin of these animals with others lower in the scale. (*Epistola de Ovi Mammalium et Hominis Genesi,* Lipsiæ, 1827. See also the interesting commentary on or supplement to the *Epistola* in Heusinger's *Journal,* and the translation in Breschet's *Répertoire,* Paris, 1829.)

In 1829 Von Baer published the first part of his great work, entitled *Beobachtungen und Reflexionen über die Entwickelungsgeschichte der Thiere,* the second part of which, still leaving the work incomplete, did not appear till 1838. In this work, distinguished by the fulness, richness, and extreme accuracy of the observations and descriptions, as well as by the breadth and soundness of the general views on embryology and allied branches of biology which it presents, he gave a detailed account not only of the whole progress of development of the chick as observed day by day during the incubation of the egg, but he also described what was known, and what he himself had investigated by numerous and varied observations, of the whole course of formation of the young in other vertebrate animals. His work is in fact a system of comparative embryology, replete with new discoveries in almost every part.

Von Baer's account of the layers of the blastoderm differs somewhat from that of Pander, and appears to be more consistent with the further researches which have lately been made than was at one time supposed, in this respect, that he distinguished from a very early period two primitive or fundamental layers, viz., the animal or upper, and the vegetative or lower, from each of which, in connection with two intermediate layers derived from them, the fundamental organs and systems of the embryo are derived:—the animal layer, with its derivative, supplying the dermal, neural, osseous, and muscular; the vegetative layer, with its derivative, the vascular and mucous (intestinal) systems. He laid down the general morphological principle that the fundamental organs have essentially the shape of tubular cavities, as appears in the first form of the central organ of the nervous system, in the two muscular and osseous tubes which form the walls of the body, and in the intestinal canal; and he followed out with admirable clearness the steps by which from these fundamental systems the other organs arise secondarily, such as the organs of sense, the glands, lungs, heart, vascular glands, Wolffian bodies, kidneys, and generative organs.

---

[1] Along with the work of W. Hunter must be mentioned a large collection of unpublished observations by Dr. James Douglas, which are preserved in the Hunterian Museum of Glasgow University.

[2] Von Baer was born in the Russian province of Esthonia in 1792, and was educated at Dorpat and in Germany. After having been fifteen years professor in the Prussian university of Königsberg, he was called to St. Petersburg, where he remained for nearly thirty years, and, as professor and member of the Imperial Academy, promoted in the most zealous and able manner, by his unexampled activity, comprehensive and original views, sound judgment, and powerful co-operation, the whole range of scientific education and biological research.

To complete Von Baer's system there was mainly wanting a more minute knowledge of the intimate structure of the elementary textures, but this had not yet been acquired by biologists, and it remained for Thomas Schwann of Liége in 1839, along with whom should be mentioned those who, like Robert Brown and Schleiden, prepared the way for his great discovery, to point out the uniformity in histological structure of the simpler forms of plants and animals, the nature of the organized animal and vegetable cell, the cellular constitution of the primitive ovum of animals, and the derivation of the various textures, complex as well as simple, from the transformation or, as it is now called, differentiation of simple cellular elements,—discoveries which have exercised a powerful and lasting influence on the whole progress of biological knowledge in our time, and have contributed in an eminent degree to promote the advance of embryology itself.

To Reichert of Berlin more particularly is due the first application of the newer histological views to the explanation of the phenomena of development, 1840. To him and to Kölliker and Virchow is due the ascertainment of the general principle that there is no free-cell formation in embryonic development and growth, but that all organs are derived from the multiplication, combination, and transformation of cells, and that all cells giving rise to organs are the descendants or progeny of previously existing cells, and that these may be traced back to the original cell or cell-substance of the ovum.

It may be that modern research has somewhat modified the views taken by biologists of the statements of Schwann as to the constitution of the organized cell, especially as regards the simplest or most elementary form, and has indicated more exactly the nature of the protoplasmic material which constitutes its living basis; but it has not caused any very wide departure from the general principles enunciated by that physiologist. Schwann's treatise, entitled *Microscopical Researches into the Accordance in the Structure and Growth of Animals and Plants*, was published in German at Berlin in 1839, and was translated into English by Henry Smith, and printed for the Sydenham Society in 1847, along with a translation of Schleiden's memoir, "Contributions to Phytogenesis," which originally appeared in 1838 in Müller's *Archiv* for that year, and which had also been published in English in Taylor and Francis's *Scientific Memoirs*, vol. ii. part vi.

Among the newer observations of the same period which contributed to a more exact knowledge of the structure of the ovum itself may be mentioned—first, the discovery of the germinal vesicle, or nucleus, in the germ-disk of birds by Purkinje (*Symbolæ ad ovi avium historiam ante incubationem*, Vratislaviæ, 1825, and republished at Leipsic in 1830); second, Von Baer's discovery of the mammiferous ovum in 1827, already referred to; third, the discovery of the germinal vesicle of mammals by Coste in 1834, and its independent observation by Wharton Jones in 1835; and fourth, the observation in the same year by Rudolph Wagner of the germinal macula or nucleus. Coste's discovery of the germinal vesicle of Mammalia was first communicated to the public in the *Comptes Rendus* of the French Academy for 1833, and was more fully described in the *Recherches sur la génération des Mammifères*, by Delpech and Coste, Paris, 1834. Thomas Wharton Jones's observations, made in the autumn of 1834, without a knowledge of Coste's communication, were presented to the Royal Society in 1835. This discovery was also confirmed and extended by Valentin and Bernardt, as recorded by the latter in his work *Symb. ad ovi Mammal. hist. ante prægnationem.* Rudolph Wagner's observations first appeared in his *Textbook of Comparative Anatomy*, published at Leipsic in 1834–5, and in Müller's *Archiv* for the latter year. His more extended researches are described in his work *Prodromus hist. generationis hominis atque animalium*, Leipsic, 1836, and in a memoir inserted in the *Trans. of the Roy. Bavarian Acad. of Sciences*, Munich, 1837.

The two decades of years from 1820 to 1840 were peculiarly fertile in contributions to the anatomy of the fœtus and the progress of embryological knowledge. The researches of Prévost and Dumas on the ova and primary stages of development of Batrachia, birds, and mammals, made as early as 1824, deserve especial notice as important steps in advance, both in the discovery of the process of yolk segmentation in the batrachian ovum, and in their having shown almost with the force of demonstration, previous to the discovery of the mammiferous ovarian ovum by Von Baer, that that body must exist as a minute spherule in the Graafian follicle of the ovary, although they did not actually succeed in bringing the ova clearly under observation.

The works of Pockels (1825), of Seiler (1831), of Breschet (1832), of Velpeau (1833), of Bischoff (1834)—all bearing upon human embryology; the researches of Coste in comparative embryology in 1834, already referred to, and those published by the same author in 1837; the publication of Joannes Müller's great work on physiology, and Rudolph Wagner's smaller text-book, in both of which the subject of embryology received a very full treatment, together with the excellent *Manual of the Development of the Fœtus*, by Valentin, in 1835, the first separate and systematic work on the whole subject—now secured to embryology its permanent place among the biological sciences on the Continent; while in this country attention was drawn to the subject by the memoirs of Allen Thomson (1831), Th. Wharton Jones (1835–38) and Martin Barry (1839–40).

Among the more remarkable special discoveries which belong to the period now referred to, a few may be mentioned, as, for example, that of the chorda dorsalis by Von Baer, a most important one, which may be regarded as the key to the whole of vertebral morphology; the phenomenon of yolk segmentation, now known to be universal among animals, but which was only first carefully observed in Batrachia by Prévost and Dumas (though previously casually noticed by Swammerdam), and was soon afterwards followed out by Rusconi and Von Baer in fishes; the discovery of the branchial clefts, plates, and vascular arches in the embryos of the higher abranchiate animals by Rathke in 1825–27; the able investigation of the transformations of these arches by Reichert in 1837; and the researches on the origin and development of the urinary and generative organs by Joannes Müller in 1829–30.

On entering the fifth decade of our century, the number of original contributions and systematic treatises becomes so great as to render the attempt to enumerate even a selection of the more important of them quite unsuitable to the limits of the present article. We must be satisfied, therefore, with a reference to one or two which seem to stand out without greater prominence than the rest as landmarks in the progress of embryological discovery. Among these may first be mentioned the researches of Theodor F. W. von Bischoff, formerly of Giessen and now of Munich, on the development of the ovum in Mammalia, in which a series of the most laborious, minute, and accurate observations furnished a greatly novel and very full history of the formative process in several animals of that class. These researches are contained in four memoirs, treating separately of the development of the rabbit, the dog, the guinea-pig, and the roe-deer, and appeared in succession in the years 1842, 1845, 1852, and 1854.

Next may be mentioned the great work of Coste, entitled *Histoire gén. et particul. du Développement des Animaux*, of which, however, only four fasciculi appeared between the years 1847 and 1859, leaving the work incomplete. In this work, in the large folio form, beautiful representations are given of the author's valuable observations on human embryology, and on that of various mammals, birds, and fishes, and of the author's discovery in 1847 of the process of partial yolk segmentation in the germinal disc of the fowl's egg during its descent through the oviduct, and his observations on the same phenomenon in fishes and mammals.

The development of reptiles received important elucidation from the researches of Rathke, in his history of the development of serpents, published at Königsberg in 1839, and in a similar work on the turtle in 1848, as well as in a later one on the crocodile in 1866,—along with which may be associated the observations of H. J. Clark on the "Embryology of the Turtle," published in Agassiz's *Contributions to Natural History, etc.*, 1857.

The phenomena of yolk segmentation, to which reference has more than once been made, and to which later researches give more and more importance in connection with the fundamental phenomena of development, received great elucidation during this period, first from the observations of C. T. E. von Siebold and those of Bagge on the complete yolk segmentation of the egg in nematoid worms in 1841, and more fully by the observations of Kölliker in the same animals in 1843. The nature of partial segmentation of the yolk was first made known by Kölliker in his work on the development of the Cephalopoda in 1844, and, as has already been mentioned, the phenomena were observed by Coste in the eggs of birds. The latter observations have since been confirmed by those of Oellacher, Götte, and Kölliker. Further researches in a vast number of animals give every reason to believe that the phenomenon of segmentation is in some shape or other the invariable precursor of embryonic formation.

A large body of facts having by this time been ascertained with respect to the more obvious processes of development, a further attempt to refer the phenomena of organogenesis to morphological and histological principles became desirable. More especially was the need felt to point out with greater minuteness and accuracy the relation in which the origin of the fundamental organs of the embryo stands to the layers of the blastoderm; and this we find accomplished with signal success in the researches of Remak on the development of the chick and frog, published between the years 1850 and 1855.

From Remak's observations it appeared that the middle layer of the blastoderm, whatever may be the precise source from which it originally springs,—a point left undetermined by Von Baer, Remak, and even by more recent observers,—becomes divided in its lateral portions into two laminæ, so as to leave between them the cavity which afterwards intervenes between the external wall and the contained viscera of the body. This cavity corresponds to the pleuro-peritoneal space of the higher animals, and may be designated in the lower by the general term of *cœlom* (Haeckel).

While, therefore, Remak recognized an outer and an inner layer of the blastoderm, corresponding only in some measure with the serous and mucous layers of Pander, he showed that the greater part of the middle layer is divided into two, the outer of which is the main source of the osseous and muscular walls of the body, and the inner is the seat of development of the involuntary contractile walls of the alimentary canal, the heart, and the principal vessels.

Thus, according to the system of Remak, while the central portion of the middle layer remains undivided, and gives rise to the axial *chorda dorsalis* or notochord, with the surrounding vertebral and cranial walls, the lateral parts of this layer are in the earlier stage of its development split into two by the formation of the pleuro-peritoneal cavity, and there thus result the four layers whose relation may, according to the light received from more recent inquiry, be tabularly represented as follows:—

Primitive Blastoderm.	Ectoderm	1. Sensorial or Epiblast................		Secondary Blastoderm.
		2, 3. Mesoderm or Mesoblast	2. Body Wall.....	
			3. Visceral Wall	
	Endoderm	4. Intestinal or Hypoblast............		

From the first of these layers (1), the *neuro-corneous* of Remak, now named epiblast, the cuticular system and central organs of the nervous system (cerebro-spinal axis) are primarily formed, and secondarily, certain parts of the principal organs of sense, viz., the eye, ear, and nose. The *motoro-germinative* is the name applied to the middle layer by Remak, of which (2), the outer division, the *volunto-motory*, corresponding to the body-wall or somato-pleure of more recent authors, furnishes the material for the development of the true skin, the voluntary muscles, and the skeleton: and (3), the inner division, the *involunto-motory*, corresponding to the visceral wall or splanchno-pleure of recent authors, is the source of formation of the contractile wall of the alimentary canal, the heart, and larger blood vessels, the vascular glands, the primordial kidneys, and the generative organs. The fourth or lowest layer (4), the *intestino-glandular* of Remak and the hypoblast of recent writers, is the source of the epithelial lining of the alimentary canal and air passages and of the cellular parts of the internal glands.

These researches of Remak appear in some measure to reconcile the views of Von Baer with those of other embryologists as to the constitution of the blastoderm and the relation of its several layers to the fundamental systems and organs of the embryo. Recent observation, though modifying them in some respects, has not led to any important invalidation of their general results; and we may therefore in the mean time regard them as forming the principal basis or starting-point of modern embryological inquiries, although much still remains to be ascertained as to the source of the mesoblast and its relation to the two primitive layers of the blastoderm. More especially important in a comparative embryological view is the formation of the *cœlom* or somato-visceral cavity, as connected with the gradual appearance in the animal series of the lymphatic and blood vascular cavities.

But while the researches of Remak and others had thus in the commencement of the sixth decade of our century brought the history of the general phenomena of development or embryogeny into a consistent and systematic form, especially as known in the higher vertebrates, much still remained to be done in the more minute investigation of the origin of the ovum and its germ, and the intimate nature of the process of fecundation, as well as in regard to the histological and morphological changes in which the organogenic processes consist. The progress of discovery in these departments has been greatly promoted by the very great improvements which have been introduced into the methods of investigation, the successful prosecution of which has had an equally favorable influence on the whole range of minute anatomy and histology, viz.:—(1), the hardening, clearing, and tinting processes of preparation; (2), the method of fine section of the parts to be observed; and (3), the permanent preservation of specimens in the moist or dried state.

The first of these methods may be said to have had its origin in the introduction of the use of chromic acid as a hardening agent by Hannover of Copenhagen in 1840; and the works on practical histology since published bear ample testimony to the prodigious advance in refinement in the adaptation of this and other methods of hardening and distinctive coloration of the tissues, which have in recent times rendered the minuter investigation of the tissues comparatively elegant and exact, and indeed now almost exhaustive.

The second method, or that of sections, as applied to embryological research, obviously suggested by the diagrams of Pander and Von Baer, seems first to have been practically applied by Allen Thomson in 1831, though without the assistance of finer modern appliances, in the ascertainment of the earliest double condition of the aorta in the bird's embryo. It was soon carried to a much greater extent by Reichert, and later by Remak, and it is now universally pursued as a principal means of embryological investigation. To show the extent to which the successful combination of the above-mentioned methods is now carried by the use of the most approved chemical reagents and the best sectional instruments, it may be stated that as many as several hundreds of perfectly clear sections may be made through the body of an embryo of only half an inch in length, and that similarly thin sections may be made in any desired direction through the smallest as well as larger ova, and that, notwithstanding the extreme delicacy of some of the parts and the inequality of their density, every one of the sections may be made to present a distinct and true view both of the microscopic histological characters and of the larger morphological relations of the parts observed.

Accordingly, during the time which has elapsed since the publication of Remak's work, the number of contributions to different parts of our subject, by the history of original observations made mainly by the way of sections, has been immense, and it goes on increasing to the present time. Among the more important of these, as influencing the general progress of embryological science, the following may be mentioned.

First, in connection with the development of Fishes, the researches of Lereboullet "On the Pike and the Perch" (*Annal* *des Sciences Nat.*, 1862); those of Joseph Oellacher "On the Trout" (*Zeitsch. für Wissensch. Zool.*, 1872); those of His also "On Osseous Fishes," appearing in 1875, and the important and elaborate researches of F. M. Balfour "On the Elasmobranch Fishes," in 1874 and following years (*Journ. of Anat. and Physiol.* and *Quart. Journal of Microscopic Anatomy*); the prize memoir of Max Schulze *On the Development of the River Lamprey*, Haarlem, 1856; and the researches of Kowalewsky "On the Development of the Amphioxus" (in the *Mem. of the St. Petersburg Acad.*, tom. xi., 1867), are deserving of notice.

Second, in regard to Amphibia, after the memoirs of Rusconi, Reichert, Remak, and C. Vogt of earlier date, the most important recent contributions are those of V. Bambecke "On the Development of Pelobates fuscus" (*Mém. de l'Acad. de Belgique*, vol. xxxiv., 1868), and the very beautiful work of C. Götte *On the Development of the Toad, Bombinator igneus* (Leipsic, 1874, folio).

Third, in regard to Reptilia, not much has been done since Rathke's work *On the Development of the Turtle* was published in 1848. But there may be mentioned as valuable contributions to this department, the *Account of the Development of the Crocodile*, by Rathke himself in 1866, and the "Embryology of the Turtle," by H. J. Clarke, in Agassiz's *Contributions to the Natural History of the United States* (vol. ii., 1857).

Fourth, in the class of Birds, the most notable work which has appeared in recent times on the earlier phenomena of their development is that of His, entitled *Researches on the First Foundation of the Body in Vertebrate Animals* (Leipsic, 1868), in which a careful revision of the subject is undertaken from original observations, and a clearer distinction established between the axial or central and the lateral parts of the blastoderm. Under this head come also the researches of Dursy upon the primitive trace of the chick (Lahr, 1866), F. M. Balfour's paper on the same subject (1873), and the important observations of Peremeschko on the formation of the layers of the blastoderm, especially the middle one (*Vienna Acad.*, 1868), Affanasieff on the first circulation in the fowl's embryo (in 1866), E. Klein on the development of blood vessels and blood corpuscles from the middle layer (1868), along with which may also be quoted the observations of Walldeyer, Oellacher, Stricker, Götte, Balfour, and Kölliker, as tending to throw light on the origin of the blastodermic layers.

Fifth, in regard to Mammalia, the most recent observations after those of Bischoff on the process of development in this class, are those of Hensen, in *Zeitsch. für Anat. und Entwickelungsgesch.*, vol. i., 1875–76; the observations of Kölliker in the new edition of his systematic work, 1876; those of Reichart, in his *Account of the Development of the Guineapig*, Berlin, 1862, and his *Description of an Early Human Product*, etc., Berlin, 1873; also in the papers of E. A. Schäfer, from *Physiol. Laborat. Univ. Coll. London*, and *Proceedings Roy. Soc.*, 1876.

On the structure and morphology of the ovum may be quoted the article "Ovum" in the *Cyclopædia of Anatomy and Physiology*, by Allen Thomson (1852–56); the contributions of Gegenbaur, 1861 and 1864, and of Cramer, 1868; and the very able "Mémoire Coronné" of Edward van Beneden, *Recherches sur la composition et la signification de l'Oeuf*, Brussels, 1870.

With respect to the progress of segmentation of the ovum and earliest steps in the formation of the germ, the most interesting researches have recently been communicated by Auerbach, Butschli, Strasburger, Edw. van Beneden, Oscar Hertwig, and others, which are still in progress, and will be referred to in the article GENERATION.

Several systematic works or text-books on embryology have appeared since it assumed the form and dimensions of a special branch of science. The first of these, by Valentin, referring to the development of man, mammals, and birds, was published in 1835. The next was that of Bischoff, published in 1842, as one of the volumes of the encyclopædic system of anatomy named after Soemmering. The third work of this kind was that of Kölliker, in the form of lectures, published in 1861, and giving a very full account of the development of the ovum and embryo in man and the higher animals. Of this work a second edition is now in progress, the first part having appeared in 1876. To this excellent work, as the production of one who has contributed a very large amount of original observations on embryology and the whole range of minute anatomy, the reader may be referred for the fullest and most accurate systematic information on the subject. In comparative embryology we have the interesting short treatise of Rathke, edited after his death by Kölliker in 1861, and the *Lehrbuch der Vergleichende Embryologie* by S. L. Schenk, Vienna, 1874. We may also refer here to the excellent plates illustrating embryology in the *Icones Physiologicæ* of A. Ecker, 1854.

In this country, since the appearance of the very careful translation of Müller's *Physiology* by Baly, which had the advantage of revision in many of its parts by Sharpey, and the translation of Wagner's *Physiology* in 1846, there has appeared only one systematic work on embryology, viz., the *Elements of Embryology* by M. Foster and F. M. Balfour, of which the first part, which appeared in 1874, treating of the development of the embryo of birds, deserves the highest praise. A short view of human embryology is given by Allen Thomson in the 8th edition of Quain's *Anatomy*, 1876.

For an account of the relation of embryology to the classification of animals and to phylogeny or the theory of descent, the English reader is referred to various parts of the writings of Darwin and Huxley, and to the excellent translation of Haeckel's work on the *History of Creation*, 2 vols., London, 1874; to F. M. Balfour's "Comparison of the Early Stages in the Development of Vertebrates" in *Journ. of Microscopical Science*, vol. xv., 1875, and to the recently published *Notes on Embryology and Classification*, by E. Ray Lankester, 1877.

In the preceding sketch of the history of the foundation and progress of the science of embryology, no attempt has been made to trace that part of it which includes the development of different invertebrate animals, as it was felt that from the extremely numerous, varied, scattered, and fragmentary nature of many of the contributions of authors in this part of our subject, any attempt at the citation even of the more important would be quite unsuitable to this work.

It will be enough for us here to state that the first considerable original work on the development of a division of the invertebrates was that of Maurice Herold of Marburg on spiders, "De generatione Aranearum ex ovo," published at Marburg in 1824, in which the whole phenomena of the formative process in that animal are described with remarkable clearness and completeness.

A few years later an important series of contributions to the history of the development of invertebrate animals appeared in the second volume of Burdach's work on *Physiology*, of which the first edition was published in 1828, and in this the history of the development of the Entozoa was the production of Ch. Theod. Von Siebold, and that of most of the other invertebrates was compiled by Rathke from the results of his own observations and those of others. These memoirs, together with others subsequently published by Rathke, entitle him to be regarded as the founder of invertebrate embryology.

It would be quite unsuitable in this article to attempt to pursue further the history of research in the embryology of invertebrate animals, as may well be seen from the following enumeration in an alphabetical order of the names of some of the more prominent original observers, to whom has been mainly due the great progress in this part of our science, viz., Agassiz, Allman, Balbiani, Edward van Beneden, P. J. van Beneden, Victor Carus, Claparéde, Cohn, Dalyell, Darwin, Dujardin, Ecker, Eschricht, Gegenbaur, Haeckel, Huxley, Kölliker, Kowalewsky, Krohn, Lacaze, Duthiers, Lereboullet, Leuckart, Leydig, Lovén, Lubbock, Metschnikoff, Milne-Edwards, H. Müller, Johannes Müller, Nordmann, Prévost, Quatrefages, Salensky, Sars, Max Schultze, Semper, Steenstrup, Stein, C. Voght, R. Wagner, Strethill Wright. But this list includes only a small part of the observers whose contributions to the knowledge of this wide field of research would require to be noticed in any account of its literature.

The most general results which are deducible from the numerous observations which are now being accumulated in this department of embryology may be briefly stated as follows.

In the Protozoa there is no true sexual generation, although in some the phenomena of conjugation form an approach to that mode of reproduction. The greater number usually multiply either by fission or by gemmation; but in some, and probably in all, reproduction also appears to take place from extremely minute particles separated from the parent animals, which can scarcely be called ova, but which, for want of a better term, we may designate germinal particles.

In all animals above the Protozoa, including the sponges, male and female reproductive elements are to be distinguished, that of the female taking the form of an ovum, in which the germinal part has the protoplasmic structure of a true organized cell.

Fecundation of the ovum takes place, as in all vertebrates, by the direct access of the substance of the male element to the germinal part of the ovum.

The first steps in the development of a fecundated ovum are in all instances among the invertebrates, just as in the vertebrates, those of cellular multiplication by fission or cleavage of the protoplasmic germ of the ovum, which results in the formation of a more or less laminar blastoderm.

This blastoderm presents at first two layers of cells, ectoderm and endoderm, in all animals above the Protozoa, and in the lowest of the Cœlenterata only two; but in all the higher animals there appears an additional intermediate layer or layers, constituting the mesoderm.

From these layers the rudiments of the several systems and organs of the body are developed by processes of cellular multiplication and differentiation according to certain histological and morphological laws essentially analogous to those which have been in part previously referred to in this article, and which will be more fully described in that on Generation.

Having now traced the principal steps by which, upon the basis of extended morphological and histological observations during a century, extending from Wolff to Darwin, the science of embryology has been securely founded, enough has been adduced to show the important place which this science must occupy in relation to other departments of biology. It will be seen that histology owes to embryological observations the greatest amount of its recent extraordinary progress. It is also apparent that many of the most important facts in physiology, especially as related to growth and nutrition, can only be understood from a full and minute acquaintance with the various changes of differentiation observed in the development of organic structure. It is equally obvious that the nature of certain kinds of congenital malformation receive their rational explanation in the knowledge of the natural organo-genetic process of development, from which they are no more than deviations in different modes and degrees. Nor can it be doubted that the arrangement of animals under an approved zoological system, in which the various affinities and gradations of their organization are fully recognized, can only be undertaken upon the basis of a complete knowledge of the metamorphoses of the young of animals and the relation of the embryonic to the adult forms of the species. Lastly, the general views which we may attempt to form of the process by which in the long lapse of time since the creation the various kinds of animals, including man, may be supposed to have originated, must be founded on the correlation of the ascertained facts of embryology, as observed in every animal species, with the fuller knowledge of the different forms and gradations of all existing animals, and with the more complete observation of the different forms of organization, the evidence of whose existence at successive periods of the earth's history is to be found in their fossil remains which are inclosed in the various strata composing its superficial crust. (A. T.)

EMDEN, formerly Embden, a maritime town of Prussia, in the district of Aurich, province of Hanover, is situated near the mouth of the Ems, on the Westphalian railway, 45 miles W.N.W. of Oldenburg. The town is much intersected by canals, and more than thirty bridges are required to connect its different parts. It has a considerable maritime trade, chiefly in corn, butter, cheese, and wood. Its industries are shipbuilding, tanning, and the manufacture of paper, cement, and tobacco. Amongst its public buildings may be named the town-house, the orphanage, the poorhouse, the museum, the great Reformed church, the gymnasium, and the deaf and dumb institute. Emden belonged originally to East Friesland. From 1595 it was a free town under the protection of Holland until 1744, when, along with East Friesland, it was transferred to Prussia, after which it came into the possession of Holland in 1806, of France in 1809, of Prussia in 1814, and of Hanover in 1815; and finally in 1866 it was, along with Hanover, incorporated with Prussia. The population of Emden in 1875 was 12,874.

EMERALD (Greek, *σμάραγδος*), a precious stone classed mineralogically with the beryl (see vol. iii. p. 530), from which, however, it differs in having a fine green color, attributed to the presence in it of chromium sesquioxide: it also never presents the internal striæ often seen in the beryl. The chemical composition of the emerald may be represented by the formula $6SiO_2,Al_2O_3,3GlO$. It occurs in six-sided prismatic crystals of the hexagonal system, the edges of which not unfrequently show various modifications. The emerald is transparent or translucent, and has a vitreous, rarely resinous lustre, an uneven and conchoidal fracture, a hardness of 7·5–8, and a specific gravity of 2·670 to 2·732. It is brittle and comparatively soft when fresh from the mine, but hardens on exposure to the air. The specific gravity of crystallized emeralds after fusion was found by Greville Williams to be 2·4, 9 per cent. of the original weight having been lost. The emerald is unaffected by acids, but with borax gives before the blowpipe a transparent greenish glass. On friction it becomes electric. Wöhler, Rose, Hofmeister, and Greville Williams have shown that the emerald may be heated to a very high temperature without destruction of its color, which cannot therefore, as supposed by Lewy, be due to the organic impurities discovered in the stone. Cleavage of the emerald at right angles to the axis of the crystals may be effected without much difficulty, and in the East, previous to about the middle of the 15th century, the stone was generally worn in slices so obtained. The finest emeralds are procured from Muzo, in Colombia (see vol. vi. p. 138). The fossiliferous character of the limestone in which they occur at Muzo, and the presence in them of from 1·65 to 2·15 per cent. of water, led Mr. Lewy to the conclusion that they must have been crystallized out of aqueous solution. Other localities are Henbachthal in Salzburg, Odontchelong in Siberia, and Canjargum in India. The emeralds of Colombia, according to Boussingault, are divided into several classes, the principal of which are the *canutillos* or the crystallized and more valuable stones, and the *morallons* or amorphous stones, poor in color, and of little value. The Hebrew word *nophech*, rendered "emerald" in the English version of the Scriptures, appears to have been the carbuncle. The emerald was highly valued by the ancients (see Pliny, *Nat. Hist.*, xxxvii. 5). Various virtues were formerly ascribed to the gem: it was said to be good for the eyes, to color water green, to assist women in childbirth, and to drive away evil spirits; and in the East it is still accredited with talismanic and medicinal properties. One of the most celebrated examples of the emerald is that in the possession of the duke of Devonshire, measuring upwards of 2 inches in length, and across its three diameters $2\frac{1}{4}$, $2\frac{1}{5}$, and $1\frac{7}{8}$ inches. Other fine stones are the Hope emerald, weighing 6 oz., and those of the Russian, Saxon, and Papal crowns. Emeralds are cut on a copper wheel with emery, and polished on a tin wheel with rotten-stone. "In a good gem," says Mr. Emanuel, "the surface must be perfectly straight and smooth, so as to cast no darkening shadow on any of its particles." The form usually given to emeralds is that of a square table with the edges replaced, the lower surface being cut into facets parallel to their sides. When fine they are always set without a foil; and, as their brilliancy is somewhat impaired by candle-light, they are generally surrounded with small diamonds or pearls, which enhance their effect. The gem has been very successfully imitated by manufacturers of paste stones, the coloring matter used being oxide of chromium. As a gem the emerald is reckoned inferior only to the diamond and ruby, but, unlike them, it does not increase in value in proportion to the cube of its weight. What is termed the Oriental emerald is a green variety of corundum, an exceedingly scarce gem.

See H. Emanuel, *Diamonds and Precious Stones*, 1865; Greville Williams, "Researches on Emeralds and Beryls," *Proc. Roy. Soc.* xxi. 1872–3, p. 409.

ÉMERIC-DAVID, Toussaint-Bernard (1755–1839), a French archæologist and writer on art, was born at Aix, in Provence, 20th August, 1755. He was destined for the legal profession, and having gone in 1775 to Paris to complete his legal education, he acquired there a taste for art which influenced his whole future career. After being made advocate, he went to Italy, where he continued his art studies. He soon returned, however, to his native village, and followed for some time the profession of an advocate; but on the death of his uncle Antoine David in 1787 he succeeded to his printing business. He was elected mayor of Aix in 1791; and although he speedily resigned his office, he was in 1793 threatened with arrest, and had for some time to adopt a vagrant life. When danger was past he returned to Aix, sold his printing business, and engaged in general commercial pursuits; but he was not long in renouncing these also, in order to devote himself exclusively to literature and art. From 1809 to 1815 he represented his department in the legislative chamber, and in 1816 he was elected a member of the Institute. He died at Paris, 2d April, 1839.

Émeric-David was placed in 1825 on the commission appointed to continue *L'Histoire littéraire de la France.* His principal works are *Recherches sur l'art statuaire, considéré chez les anciens et les modernes*, Paris, 1805, a work which obtained the prize of the Institute; *Suite d'études calquées et dessinées d'après cinq tableaux de Raphael*, Paris, 1818–21, in 6 vols. fol.; *Jupiter, ou recherches sur ce dieu, sur son culte*, etc., Paris, 1833, 2 vols. 8vo, illustrated; and *Vulcain*, Paris, 1837.

EMERSON, William (1701–1782), an eminent but eccentric mathematician, was born May 14, 1701, at Hurworth, near Darlington, where his father Dudley Emerson, also a mathematician of high attainments, taught a school. From him young Emerson received a thorough mathematical education, and the bequest of a good mathematical library. For his classical training he was indebted to the curate of Hurworth, who lodged in his father's house. In the earlier part of his life he followed his father's profession, but with little success; and this, coupled with the fact of his having received as an only child a moderate competence from his parents, led him to devote himself entirely to studious retirement. Towards the close of 1781 he relinquished his studies and disposed of his library. His death took place soon after, May 20, 1782, at his native village, in the eighty-first year of his age. Emerson in dress, manners, and appearance was eccentric and indeed clownish, but he possessed remarkable independence of character, and intellectual energy of a very high order. The boldness with which he expressed his opinions on religious subjects led to his being charged with scepticism, but for this there was no foundation. He invariably shut himself up in London during the publication of his works, and carefully revised them sheet by sheet himself, so that they are singularly free from errata. In mechanics, he never advanced a proposition which he had not previously tested in practice, nor published an invention without first proving its effects by a model. Emerson was married, but had no family. His wife employed her leisure in spinning on a curious wheel, of which an accurate drawing is given in his *Mechanics.* His own favorite recreation was fishing. He was skilled in the science of music, the theory of sounds, and the ancient and modern scales; but he never attained any excellence as a performer.

The following is a list of Emerson's works:—*The Doctrine of Fluxions*, 1748, 8vo; *The Projection of the Sphere, orthographic, stereographic, and gnomical*, 1749, 8vo; *The Elements of Trigonometry*, 1749, 8vo; *The Principles of Mechanics*, 1754, 8vo; *A Treatise of Navigation*, 1755, 12mo; *A Treatise of Algebra*, in two books, 1765, 8vo; *The Arithmetic of Infinites, and the Differential Method, illustrated by Examples*, 1767, 8vo; *Mechanics, or the Doctrine of Motion*, 1769, 8vo; *The Elements of Optics, in four books*, 1768, 8vo; *A System of Astronomy*, 1769, 8vo; *The Laws of Centripetal and Centrifugal Force*, 1769, 8vo; *The Mathematical Principles of Geography*, 1770, 8vo; *Tracts*, 1770, 8vo; *Cyclomathesis, or an easy Introduction to the several branches of the Mathematics*, 1770, in ten vols. 8vo; *A short Comment on Sir Isaac Newton's Principia;* to which is added, *A Defence of Sir Isaac against the objections that have been made to several parts of his works*, 1770, 8vo; *A Miscellaneous Treatise containing several Mathematical Subjects*, 1776, 8vo.

EMERY (Greek, *σμύρις*; Spanish, *esmeril*), an impure variety of the mineral corundum, bluish-gray to brownish in color, dimly translucent, and granular and rough in fracture, and having a hardness of 9, and specific gravity varying between 3·7 and 4·3. Much of the emery of commerce is artificially colored of a rich reddish brown. Analyses of emery show a percentage composition of from about 60 to 80 per cent. of alumina, and 8 to 33 per cent. of ferric oxide, with small quantities of lime, silica, and water. It occurs in amorphous masses in schists, gneiss, granular limestone, and other crystalline rocks, and in rolled and detached pieces and in granules in soils. The principal European source of emery is the island of Naxos, which in 1872 exported to England 1270 tons, to Hamburg 250 tons, and to Rotterdam 300 tons of the mineral. It occurs also near Smyrna, and in Sweden, Saxony, Spain, Greenland, Massachusetts, and other localities. Emery is used as a polishing material for plate glass, crystal, lapidaries' work, and metals, and in cutting granite and marble. It is prepared for use by breaking with hammers, crushing with steel stamps, and sifting. Combined with leather by the American "tanite" process, or treated after Ransome's method for the manufacture of artificial stone (see Concrete, vol. vi., p. 216), emery powder is formed into grinding wheels, hones, and similar instruments. Emery, more especially that used for emery-paper and emery-cloth, is commonly adulterated with garnet, zircon, iron-slag, and other substances harder than quartz sand.

EMETICS, substances which are administered for the purpose of producing vomiting. They are usually regarded as of two varieties, viz., those which produce their effect in virtue of their absorption into the blood and consequent influence upon the nerve centres, and those which act topically on the mucous membrane of the stomach, giving rise to vomiting as the result of reflex action. The former class of emetics are slower in their operation and are attended with much greater depression of the system and antecedent nausea than the latter, the action of which is prompt. The use of emetics in medicine is comparatively rare, although at one time they were often resorted to in the early stages of acute diseases, such as fevers and inflammations, with the object of cutting them short. Their power, however, to accomplish this is more than questionable. Among the purposes for which emetics are employed are the following—to empty the stomach in certain cases of poisoning, such as by narcotics or where indigestible substances are giving rise to disturbance which calls for their removal, and to clear the air passages of obstructions, as in certain cases of bronchitis or croup, where the respiratory tubes become filled with morbid material which threatens death by asphyxia, and which cannot be dislodged by coughing. For both these purposes the stimulating emetics are to be preferred, such as the sulphates of zinc and copper, or, where these are not available, mustard stirred into water. Again, emetics are employed in producing, short of their emetic action, a certain degree of nausea and consequent relaxation during the early stages of acute inflammation in strong persons, and for this purpose the more depressing emetics are resorted to, such as antimony, ipecacuanha, apomorphia, etc. The latter are likewise employed in obstetric practice with the view of producing relaxation in cases of protracted labor from uterine and muscular rigidity. Emetics ought always to be administered with caution, since the act of vomiting may be attended with danger where there exists any tendency to brain disease or in cases of disease of internal organs; or further, from the vomiting continuing longer than was intended, injury may be done to the mucous membrane of the stomach as well as serious shock inflicted on the system.

EMEU, evidently from the Portuguese *Ema*,[1] a name which has in turn been applied to each of the earlier-known forms of Ratite Birds, but has in all likelihood finally settled upon that which inhabits Australia, though, until less than a century ago, it was given by most authors to the bird now commonly called Cassowary—this last word being a corrupted form of the Malayan *Suwari* (see Crawfurd, *Gramm. and Dict. Malay Language*, ii. pp. 178 and 25), apparently first printed as *Casoaris* by Bontius in 1658 (*Hist. nat. et. med. Ind. Orient.* p. 71).

The Cassowaries (*Casuariidæ*) and Emeus (*Dromæidæ*) —as the latter name is now used—have much structural resemblance, and form the Order *Megistanes*,[2] which is peculiar to the Australian Region. Professor Huxley has shown (*Proc. Zool. Soc.* 1867, pp. 422, 423) that they agree in differing from the other *Ratitæ* in many important characters, into the details of which it is now impossible to enter; but one of the most obvious of them is that each contour-feather appears to be double, its *hyporrhachis*, or aftershaft, being as long as the main shaft—a feature noticed in the case of either form so soon as examples were brought to

---

[1] By Moraes (1796) and Sousa (1830) the word is said to be from the Arabic *Na'âma* or *Na'êma*, an Ostrich (*Struthio camelus*); but no additional evidence in support of the assertion is given by Dozy in 1869 (*Glossaire des mots espagnols et portugais dérivés de l'arabe.* Ed. 2, p. 260). According to Gesner in 1555 (lib. iii. p. 709), it was the Portuguese name of the Crane (*Grus communis*), and had been transferred with the qualifying addition of "*di Gei*" (*i.e.*, Ground-Crane) to the Ostrich. This statement is confirmed by Aldrovandus (lib. ix. cap. 2). Subsequently, but in what order can scarcely now be determined, the name was naturally enough used for the Ostrich-like birds inhabiting the lands discovered by the Portuguese, both in the Old and in the New World. The last of these are now known as Rheas, and the preceding as Cassowaries.

[2] *Ann. and Mag. Nat. Hist.* ser. 4, xx. p. 500.

Europe. The external distinctions of the two families are, however, equally plain. The Cassowaries, when adult, bear a horny helmet on their head, they have some part of the neck bare, generally more or less ornamented with caruncles, and the claw of the inner toe is remarkably elongated. The Emeus have no helmet, their head is feathered, their neck has no caruncles, and their inner toes bear a claw of no singular character.

The type of the *Casuariidæ* is the species named by Linnæus *Struthio casuarius* and by Latham *Casuarius emeu.* Vieillot subsequently called it *C. galeatus*, and his epithet has been very commonly adopted by writers, to the exclusion of the older specific appellation. It seems to be peculiar to the island of Ceram, and was made known to naturalists, as we learn from Clusius, in 1597, by the first Dutch expedition to the East Indies, when an example was brought from Banda, whither it had doubtless been conveyed from its native island. It was said to have been called by the inhabitants "Emeu," or "Ema," but this name they must have had from the earlier Portuguese navigators.[1] Since that time examples have been continually imported into Europe, so that it has become one of the best-known members of the sub-class *Ratitæ*, and a description of it seems hardly necessary. For a long time its glossy, but coarse and hair-like, black plumage, its lofty helmet, the gaudily-colored caruncles of its neck, and the four or five barbless quills which represent its wing-feathers, made it appear unique among birds. But in 1857 Dr. George Bennett certified the existence of a second and perfectly distinct species of Cassowary, an inhabitant of New Britain, where it was known to the natives as the *Mooruk*, and in his honor it was named by Mr. Gould *C. bennetti.* Several examples were soon after received in this country, and these confirmed the view of it already taken. Of late years a considerable number of other species of the genus have been described (see BIRDS, vol. iii. p. 642, note) from various localities in the same Subregion.[3] Conspicuous among them from its large size and lofty helmet is the *C. australis*, from the northern parts of Australia. Its existence indeed had been ascertained, by the late Mr. T. S. Wall, in 1854, but the specimen obtained by that unfortunate explorer was lost, and it was not until 1867 that an example was submitted to competent naturalists.

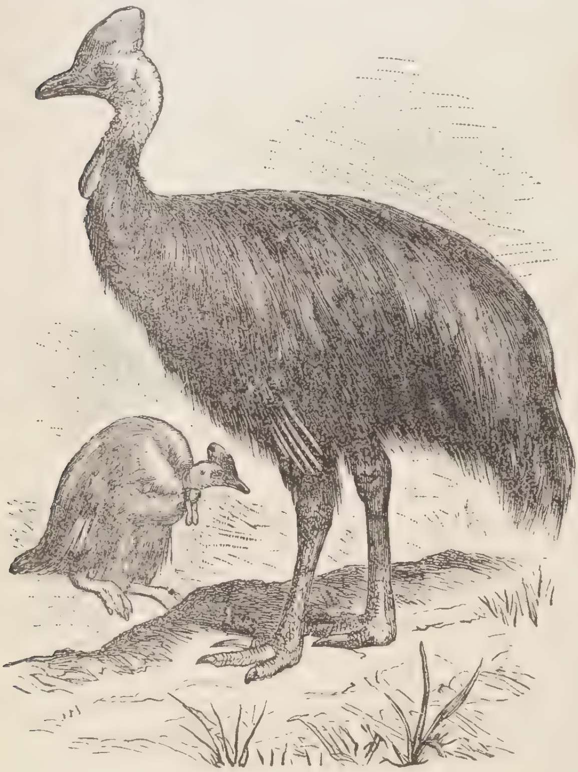

FIG. 1.—Ceram Cassowary.[2]

Not much seems to be known of the habits of any of the Cassowaries in a state of nature. Though the old species occurs rather plentifully over the whole of the interior of Ceram, Mr. Wallace was unable to obtain or even to see an example. They all appear to bear captivity well, and the hens in confinement frequently lay their dark-green and rough-shelled eggs, which, according to the custom of the *Ratitæ*, are incubated by the cocks. The nestling plumage is mottled (*Proc. Zool. Soc.* 1863, pl. xlii.), and when about half grown they are clothed in dishevelled feathers of a deep tawny color.

Of the Emeus (as the word is now restricted) the best known is the *Casuarius novæ-hollandiæ* of Latham, made by Vieillot the type of his genus *Dromæus*,[4] whence the name of the family (*Dromæidæ*) is taken. This bird immediately after the colonization of New South Wales (in 1788) was found to inhabit the south-eastern portion of Australia, where, according to Hunter (*Hist. Journ.*, etc., pp. 409, 413), the natives call it *Maracry, Marryang*, or *Maroang;* but it has now been so hunted down that not an example remains at large in the districts that have been fully settled. It is said to have existed also on the islands of Bass's Straits and in Tasmania, but it has been exterminated in both, without, so far as is known, any ornithologist having had the opportunity of determining whether the race inhabiting those localities was specifically identical with that of the mainland or distinct. Next to the Ostrich the largest of existing birds, the common Emeu is an inhabitant of the more open country, feeding on fruits, roots, and herbage, and generally keeping in small companies. The nest is a shallow pit scraped in the ground, and from nine to thirteen eggs, in color varying from a bluish-green to a dark bottle-green, are laid therein. These are hatched by the cock-bird, the period of incubation lasting from 70 to 80 days. The young at birth are striped longitudinally with dark markings on a light ground. A remarkable structure in *Dromæus* is a singular opening in the front of the wind-pipe, communicating with a tracheal pouch. This has attracted the attention of several anatomists, and has been well described by Dr. Murie (*Proc. Zool. Soc.* 1867, pp. 405–415). Various conjectures have been made as to its function, the most probable of which seems to be that it is an organ of sound in the breeding-season, at which time the hen-bird has long been known to utter a remarkably loud booming note. Due convenience being afforded to it, the Emeu thrives well, and readily propagates its kind in Europe. It is the only form of Ratite bird which naturally takes to the water, and examples have been seen voluntarily swimming a wide river.

The existence in Australia of a second species of *Dromæus* had long been suspected, and Broderip in 1842 stated (*Penny Cyclop.* xxiii. p. 145) that Mr. Gould had even supplied a name (*D. parvulus*) for it; but there can be little doubt that this suggestion was founded on a mistake. However, in 1859 Mr. Bartlett described, under the name of *D. irroratus*, what has since been generally admitted to be a good species, and it now seems certain that this fills in the western part of Australia the place occupied by the older-known form in the eastern. It is a more slender bird, and when adult has the feathers barred with white and dark-gray ending in a black spot which has a rufous margin, while those of *D. novæ-hollandiæ* are of a uniform blackish-gray from the base to near the tip, which is black with a broad subterminal rufous band. Both species have been figured by Mr. Sclater from admirable drawings by Mr. Wolf (*Trans. Zool. Soc.* iv. pls. 75, 76), and interesting particulars as to their domestication in England are given by Mr. Harting (*Ostriches and Ostrich Farming*, pp. 131–174). (A. N.)

---

[1] It is known that the Portuguese preceded the Dutch in their voyages to the East, and it is almost certain that the latter were assisted by pilots of the former nation, whose names for places and various natural objects would be imparted to their employers (see DODO, vol. vi. : p. 279).

[2] The figures are taken, by permission, from Messrs. Mosenthal and Harting's *Ostriches and Ostrich Farming*, Trübner & Co., 1877.

[3] The enterprise of travelling naturalists in New Guinea and its adjacent islands has recently been so great that the list given in the passage above referred to is already out of date, and it seems at present hardly possible to place the exact state of our knowledge of the species of *Casuarius* before the reader. Several of them have been described from immature examples living in menageries, which have not always lived to assume the characteristics of the adult, and a comparison of such examples has not in every case been practicable. Moreover, the precise localities whence some of them have been brought have perhaps been wrongly assigned. The promised work of Prof. Salvadori on the ornithology of New Guinea will very likely clear up many points that are now open to doubt; and though it is probable that in some instances the same species has been designated by more than one name, it cannot be maintained that every existing species has been brought to our knowledge.

[4] The obvious misprint of *Dromeicus* in this author's work (*Analyse*, etc , p. 54) has been foolishly followed by many naturalists, forgetful that he corrected it a few pages further on (p. 70) to *Dromaius*—the properly Latinized form of which is *Dromæus.*

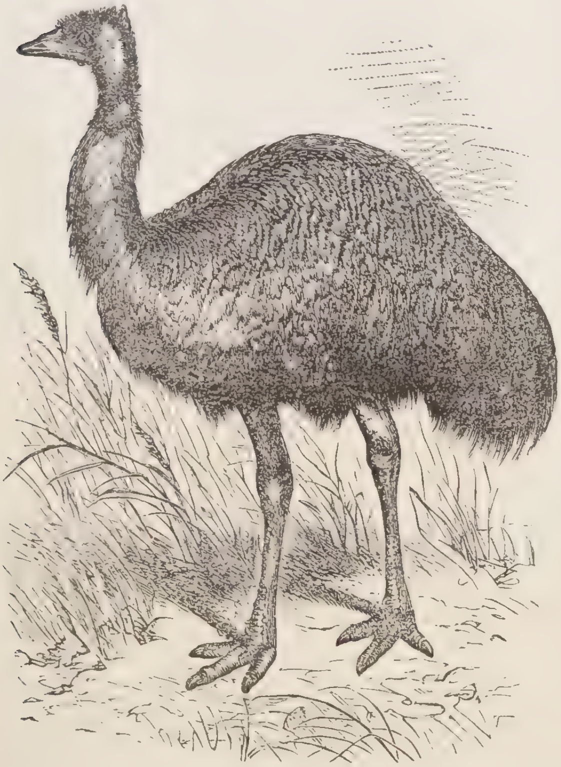

FIG. 2.—Emeu.

EMIGRATION, now one of the most constant and orderly movements of human society, must have been one of the earliest, however irregular, of human impulses. It is the act of men, families, tribes, or parts of tribes, leaving the place of their birth with the view of settling in some other place. They are emigrants in the country they leave, and immigrants in the country they pass into. But this converse nomenclature describes an identical class of persons and the same kind of adventure, more necessary now than ever to be distinguished from migrations within a given territory, or the frequent travellings between distant countries in which many engage, whether on purposes of business or pleasure. Emigration is a going out with a design of permanently settling in new seats of residence, labor, trade, and society. It is the practical response which mankind have given in all ages to the command to "multiply, and replenish the earth, and subdue it;" or, in other words, it is a necessary result of the increase of population within a limited though cherished space, and of the appointed destiny of our race to people and develop the world.

The natural law of population, though probably the deep underlying force of all emigrations, is not the only force at work in the general movement by which people, and races of people, have migrated from one part of the world to another. Not only famines, which may be said to present the pressure of population in its intensest form, but wars of official conquest and ambition, religious persecutions and religious phantasies, civil broils and political revolutions, the discovery of gold and silver mines, the envy of more genial climes and fertile lands than people have been born to, the individual love of change and adventure and pushing one's fortune, have considerable power in promoting emigrations, apart from the rude pressure of physical wants. Famines in India, for example, do not result in much emigration; and yet the Irish famine in 1846–7 led immediately to one of the most remarkable removals of persons and families from one hemisphere to another in modern times. It would be difficult to account by the law of population for the successive immigrations of Saxons, Danes, and Normans into England, or to maintain that it was a force of hunger only which impelled the Northern barbarians to attack the Roman Empire. In the invasion of Turkey in 1877 the Russian soldiers are said to have been surprised at the plenty of the Bulgarian towns and villages, and to have had curious reflections why they should have been led so far afield to battle for the relief of a population so much more comfortably bestowed than themselves. Yet when the Russian soldiers return to their comparatively sterile homes, having seen the abundance of grain and fruits and flowers on the slopes of the Balkans, their accounts will probably only increase the Muscovite passion to penetrate by force of arms into more productive regions than those of Northern Europe and Asia. We must allow, in short, for many causes of emigration, as well as many wrong views of the means by which the advantages of emigration are to be realized.

The passage of Scripture which relates what took place between Abraham and Lot in the plains of Bethel, adduced by J. R. M'Culloch in the article "Emigration" in the last edition of this work, will always remain a strikingly natural and suggestive picture of the outward movement of society in its primitive elements. There was no want apparently of material resources. "Is not the whole land before thee?" were the words of Abraham; and Lot, lifting up his eyes, saw the plain of Jordan unoccupied and well-watered. But there was strife among the servants, quarrels as to pasturings and waterings, with Canaanites and Perizzites dwelling in the land as an additional element of disorder. The kinsmen could not agree, or adjust their rule; and separation would be judicious, if not necessary. The narrative exhibits the influence of individualism on human affairs—on the affair of emigration as on others. In early times it was found difficult or impossible to make any important progress on the basis of social unity.

Nomads taking possession of vacant territory or invading the territory of others, victorious kings carrying whole tribes or nations into captivity, citizens driven out of civilized states by political rage, or attracted to adjacent lands by the promised wealth of agriculture or trade, and colonies more or less officially organized in the track of war and conquest, are the pictures we have of emigration in the ancient world.

> "Many of the emigrants from the Greek States," as Mr. M'Culloch wrote in the article above referred to, "consisted of citizens forced by the violence of contending factions to seek new settlements in other countries. But Greece also sent forth emigrants, impelled by the difficulty of maintaining themselves at home, or allured by the glowing descriptions of the comparative abundance they would enjoy in distant lands. Both these classes of emigrants established themselves, for the most part, either in countries with a scanty population, or whose inhabitants were in a decidedly lower state of civilization. And the greater refinement and ingenuity of the Greeks, and their industrious habits, enabled them to make a rapid progress, so that several of these colonies became, in no very lengthened period, populous and powerful states.
>
> "Few voluntary emigrants ever left Rome. The colonies which she sent forth were intended to bridle subjugated provinces, and should be regarded rather as the outposts of an immense army, the headquarters of which were at Rome, than as establishments of individuals who had bid adieu to their mother country, and who intended to maintain themselves in their new residence by their own industry.
>
> "But in their wish to amend their condition, emigrants have not always been contented to establish themselves in unoccupied or thinly-peopled countries. Sometimes, as in the case of the irruption of the northern nations into the Roman Empire, they have attacked countries that were densely peopled, and, having subdued the inhabitants, have seized upon the whole, or upon a greater or less proportion of their lands.
>
> "Pastoral nations, inasmuch as they can carry with them the flocks and herds from which they derive their subsistence, may emigrate in very large bodies, and previously to the invention of gunpowder and other improvements in warfare were very dangerous neighbors. The danger was further increased, or rather was perpetually kept up, by the fact that the emigration

> of one tribe or nation, by making more room for those that remained behind, gave a corresponding stimulus to population, so that, the vacuum being soon filled up, the motive to fresh emigration became as great as ever. On this principle we are able to account satisfactorily for the successive swarms of barbarians that, issuing from the countries in the north of Europe, first attacked and ultimately overthrew the colossal fabric of Roman power. It admits of demonstration that these countries were then not nearly so populous as at present, that they had not more, perhaps, than a fifth or a sixth part of the inhabitants by which they are now occupied. But as they depended principally on pasturage, their numbers were often in excess compared with their means of support. And the pressure of want, that is, the necessity of finding additional room for their flocks and herds on the one hand, and, on the other, the prospect of vast wealth and riches of which they might hope to possess themselves, precipitated them into those expeditions in which, though often defeated, they were in the end successful.”

A movement which is to be recognized as one of the necessary conditions of human progress is thus seen advancing in its early history from a collision of interests, and receiving both impulse and advantage from all the discords, wars, and difficulties of social and political life. It may be presumed, notwithstanding the imperfect civilization of many large regions of the world, that emigration has now attained so many ways and means, and so well-established an order, as to proceed more spontaneously and functionally, and be less indebted to violent forces for its impulsion than in past times. The striking modern form of emigration is the removal of individuals and families from their native seats to distant countries, in large numbers, yet without concert and without apparent distress, silently and intelligently, the emigrants knowing what they are leaving and whither they are going. Emigration of this kind, like the commerce in commodities, does not advance rapidly for a long period. The first adventurers have often a rough experience, and do not invite others, but gradually the number who succeed increases, and in their letters home encourage relatives and friends to follow their example, and not unfrequently supply the means of acting upon their advice. This, in a constant and cumulative form, comes to have more real and wholesome influence than all the emigration aid societies ever established, however useful these may have been in their place. The traffic of the steam navigation companies during the last twenty-five years would show how largely the volume of free and well-considered emigration has thus been increased; and, indeed, it may be observed that emigration of this kind has received much the same impetus as material commerce from the ocean steamers, railways, telegraphs, and other greatly improved means of transmission. The movement is liable to its own fluctuations; it ebbs and flows from one year to another; but of its permanence and extension there can be no reasonable doubt.

Trite as this may appear, it is worthy of being observed how rapidly the change has been evolved. In the thirty years from 1815 to 1845 the annual emigration from the United Kingdom to all parts had not increased to 100,000 souls. The total number of emigrants in 1815 was only 2081, in the following year 12,510, and 20,634 in 1817. This was the starting-point on the close of the great European wars; and at the end of thirty years of peace, what progress had been made? In 1843 the total number of emigrants from the United Kingdom was 57,212; it was 70,686 in 1844, and 93,501 in 1845. Only in three years of the long interval, viz., 1832, 1841, and 1842, had the annual emigration risen to or above 100,000. But 1847, in which year the emigration rose to 258,270, marks the beginning of unwonted increase, sustained over many years in succession, and, with some exceptional years, sustained, indeed, to the present time. The average annual emigration in the five years ending 1853 was 323,002, whereas from 1815 to the same year 1853 it had only been 97,269. The Irish famine, ensuing on an almost total failure of the potato crops, was the first in the order of events to which this remarkable increase of emigration is to be ascribed; but the Californian and Australian gold discoveries, the political reaction caused by the *coup d'état* in France, the failure of the European revolutions of 1848, and the rising spirit of enterprise and growing prosperity following on the adoption of free trade in the United Kingdom, by which the industry and production of all the emigrant-receiving countries were largely promoted, prolonged the impulse which had first been given by a sharp distress affecting more parts of Europe than Ireland, and placed emigration on the more voluntary and substantial basis which has characterized it of late years. The way was made so plain by the ocean steamers and railways, which trade and capital were bringing into rapid action, that larger numbers of people saw the advantage of passing over great distances from one hemisphere to another. It was not till 1855 that any relapse occurred in the large annual totals of emigration from the United Kingdom; and so late as the five years 1869–73 the average number per year of emigrants from British ports was 274,645.

This increase of emigration was not confined to the United Kingdom. It was European; and, indeed, our emigration statistics always include some proportion of emigrants from neighboring countries, who ship from British ports. But from the north of Europe—from Scandinavia and Germany—there has been a largely increased emigration during this period, proceeding under much the same incitements and facilities as from England, Scotland, and Ireland. From France the emigration has not been so marked as from many less populous countries. The German race have peopled the United States so largely as to have become a prominent element in the Transatlantic republic; but no one hears of the French as one of the constituents of a commonwealth which they helped materially to found, and where they must always be held in esteem. The emigration of France follows her own colonies and traditions chiefly; it is found in Louisiana and in Canada, and almost everywhere discursively and thinly; and in much the same way the Spaniards and Italians still lean in their emigration to La Plata and South America, where there is a trace of ancestry, and their language is spoken. The industrial motive and faculty, however, now draw emigrants from all the European nations into the most various parts of the New World. In Australia and other southern climes, where the grape has found an extended cultivation, Rhineland and Cisalpine vine-dressers are at work. The Highland Scotch cling to Canada, and prefer New-Zealand to the Australian mainland; but the engineers of the Lowland Clyde, ubiquitous as their ships, are found wherever a steamer plies or a hammer sounds on the sea-washed surface of the globe. To complete this sketch it must be added that the Chinese—the most numerous while the most isolated nationality in the world—have also become emigrants in large numbers, though it may be doubted whether the Chinese immigration to the Pacific coast of the United States has as its object a permanent change of country, or differs yet at least essentially from the coolie migrations from India and China to the Eastern Archipelago, or of South Sea Islanders to Queensland and other parts of Australia, which are more of the nature of a transfer of labor for a term of years than a definite emigration of both sexes and of families. The number of Chinese in the United States, according to the census of 1870, was 63,199, and in the Australian colony of Victoria at the same period, 17,935—in both cases nearly all males. In an elaborate report on coolie emigration from India by Mr. Geoghegan, presented to Parliament in 1874, it appears—to take Ceylon as an example—that in the ten years ending 1869 the average annual number of persons removing from Madras to that island was 65,000 (of whom 50,000 were adult males), and that the average annual number who returned from Ceylon to Madras was 48,000. A constant coming and going is the feature of all coolie emigration, whether from India or from China. The Chinese have a superstitious desire to die within the borders of their own sacred land. Nevertheless, their strong and persistent movement to the Western world is a significant phenomenon. It has broken through all restraints at home, and it has held its ground, in the face of no little social hostility, from San Francisco to New York and other cities on the Atlantic seaboard.

Foreign and colonial emigration, in short is now so widely practised, and has been rendered by improved means of transit so safe and expeditious, that its continued progress is not only sure, but one may foresee, from the various forces in play, that at no distant time it will have become, over the largest portion of the world, as familiar as migration from one province of the same country to another. The attitude and duties of states, and of the populations of states, towards a movement which comes into contact at many points with existing laws and interests—laws of naturalization, military conscription, and allegiance, with asserted rights of labor, and with social, religious, and international prejudices—have thus become questions of much importance.

Nothing is more certain than that nearly all the old countries suffered in past times from want of emigration, unless it be that all the new countries have greatly benefited by it. Leaving China out of view, where foreign immigrants have only been tolerated under treaties extorted by force of arms, there has been a general approval of emigration on the one hand, and of immigration on the other. In the United Kingdom the population are singularly free to choose either their own country or its colonies or other countries as the place of their abode. They are under no compulsory military service; and emigration has been actively encouraged by societies and protected by the Government for half a century. The greatest obstacle to free emigration from the Continent would appear to be the system of military conscription. Every German of twenty or twenty-one years is liable to personal service in the standing army for seven years—three of active service, four in the reserve—and to other five years in the landwehr, with the landsturm behind the landwehr making further demands on the time and liberty of the subject. In France a similar system is now enforced, though under more liberal exemptions. It is but fair to state that Germany, exclusive of Prussia, has up to this time been sufficiently free in its emigration to have sent to the United States, from 1820 to 1870, not fewer than 2,267,500 persons, which is nearly as many as have gone from Ireland to the United States in the same half century, viz., 2,700,493. But from Prussia, where the conscription has been longest in rigorous operation, the number of emigrants to the United States, in the same period has been only 100,983, and from France 245,812. Though the conscription may not be the sole cause of this, yet the demands made by the great military powers on the drilling and fighting services of the whole youth and manhood of their populations are obviously obstructive to the pursuit of industry and fortune in foreign countries or in colonies. These demands may be relaxed from time to time, while the system itself is maintained; but they are relaxed with a grudge, and the Governments acquire inordinate ideas of the irrevocable allegiance of their subjects. If the latter are permitted to emigrate it is under condition of being liable to recall on brief notice to the standards of their country; and an armed truce, such as has prevailed in the most civilized nations of the Continent of Europe during five or six years of peace, might soon be as detrimental to free emigration as war itself, under which it usually ceases for the time. From Russia none can emigrate without permission of the czar; and a similar despotism over the subject is the rule of the Ottoman empire. A state may be within its reasonable and proper line of duty in promoting and aiding either emigration or immigration. But that the permission of the state should be necessary to the one process or the other is inconceivable, save in some rare and dire emergencies of war or politics.

The duty of states in regard to emigration, viewed in what must now be the generally accepted light of a necessary and wholesome function of the general economy, thus resolves itself into a duty of regulation and guardianship under the two categories, always presented, of the countries which the emigrants leave, and the countries to which they go. The one are bound to see that emigrant ships are well found and not overcrowded, and that adequate arrangements are made for the provisioning, health, and safety of the passengers in their transit; while the other are bound to give them shelter and guidance on landing, to protect them from imposture, and to see that all pre-engagements made with them be fulfilled. The commission of emigration in the United Kingdom, early established as a branch of the colonial office, has labored diligently in introducing care and order into the sphere of foreign and colonial emigration, as well as into the coolie immigration of the Eastern seas. The regulations in the British home and colonial ports are embodied in two Acts of Parliament, called the Passengers Acts 1855 and 1863, which contain the administrative code on this subject in its statutory detail—only for "Commissioners of Emigration" must now be read "Board of Trade," the supervision of emigrant ships having devolved on that department in connection with the general merchant shipping. Of the regulations for the reception of immigrants, on the other hand, the arrangements at New York afford probably one of the best examples. If no country has had more to do with the shipping of emigrants than the United Kingdom, no place has had more to do with their reception than the great American seaport; and measures have been adopted there by which the abuses once prevailing have been overcome, and at the same time all the arrangements for the comfort, security, and guidance of immigrants have been placed on a satisfactory basis. Emigrant ships are visited six miles from the port by health officers, and any who may be sick or diseased are removed to hospitals under the care of the commissioners of emigration or the quarantine commission. The others are required to land at Castle Garden, where there is a large rotunda capable of accommodating 4000 persons, and where every immediate want of the immigrants may be supplied without leaving the dépôt. Letters may be written for them, or telegrams despatched to friends, or friends may be introduced immediately on their credentials being presented. The utmost care is taken to guard the immigrants from falling into bad hands, and every information is afforded them as to how they shall best proceed in their respective objects. The supervision thus exercised in the port is extended over the railways to the various parts of the Union to which immigrants may be bound. Besides such arrangements, no less honorable to the authorities of a country than encouraging to the emigrant, direct inducements have frequently been held out to settlers, both in the United States and the British colonies, in the form of grants of land or land at a cheap price, and in assisted or free passages. Unless it be when emigrants move in a large group or body, with the view of settling together in one place, a free grant of land may prove illusory, from not being suited to the industrial aptitudes of the emigrant or not situated in a locality where he would choose to reside. But when the Government of a state or colony offers assisted or free passages, it may be safely concluded that there is immediate demand for the services of the emigrants; and, as in such cases the classes of work-people required are usually specified, there is an additional security against misunderstanding or misadventure. It may be observed that Her Majesty's commissioners of emigration will not advise intending emigrants where they should go or where their particular qualifications or occupations are in most demand; but they will sometimes warn intending emigrants where they should not go, and much evil might occasionally be averted were an appeal made to this negative advice, more especially when tempting offers and attractions are presented from quarters of the world in which the failures of emigration have hitherto been much more frequent than the successes.[1]

The discussions thirty or forty years ago on organized methods of colonization have mostly disappeared in these later times. We hear no more of Mr. Wakefield's scheme, though it was useful in familiarizing the public mind with the conditions of settling population successfully on distant and unoccupied territories. When a Highland community was evicted from its native glen in Scotland, or a Highland clan was paralyzed by the bankruptcy and ruin of its chief, it contributed to their successful establishment in Canada that they emigrated in a body, with such ties of kindred and loyalty as remained. Again, at the present day, the solitary Icelanders, moved by a spirit of emigration from the volcanic rock and desert to which their ancestors were driven by despotism—and the Mennonites, invited into Russia by Paul to lay the foundation of the great wheat trade of Odessa, and now under expulsion by Alexander II. for refusing to bear arms, on the grounds of their original contract and conscientious scruples, are settling, in successive groups, with much promise of future happiness, in the Canadian province of Manitoba. From these and similar instances one can readily perceive the utility of organized emigration, and can scarcely doubt, so various and changeful is the condition of many isolated populations of the world, that it will long be a subject of practical study. But the reason, apparently, why modes and theories of colonization have almost passed out of the sphere of politics is that colonies are now so numerous and well established, and the means of entering into their social and industrial life so easy, that the consideration of initial forms has in great measure been superseded. Emigration moves of itself over vast areas of population, subject to commercial and social causes in various parts of the world; and the duty of states is chiefly to give it outlet, and as much security as good administration can supply.

---

[1] Those who may have occasion to pursue the details under this head are referred to an official publication of Her Majesty's emigration commission, entitled "No. 34, Colonization Circular—1877," in which will be found the spirit of nearly all the statutes (550) of states and colonies with which the emigration of the United Kingdom is related.

The question whether countries receiving emigrants may not be called upon in some cases to check the flow of immigration within their borders is less free of difficulty than any similar question as regards the countries from which emigrants proceed. An example of what may happen has been seen in the Mormonism of the United States, where the settlers were not only at variance with the republic on so cardinal a point as the civil law of marriage, but at open war with the federal jurisdiction and sovereignty of the soil. Similar perplexities might arise from a large Chinese or other heathen immigration, introducing customs and observances which, though called religious and claiming toleration, could only be regarded as contrary to civil order, morality, and decency. Some dilemma of the same sort may even occur in the emigrant-giving countries, as, for instance, when trades-unionists, while deriving all the benefit of a large outward flow of labor, fall upon foreign workmen who immigrate into the United Kingdom with a violence and disorder which the law has not yet learned or been able to prevent.

The statistics of emigration and immigration are copious enough, but being variously recorded by the numerous states and colonies, it is no easy task to bring them together in a general table, or to reduce them within moderate compass. The countries receiving emigrants are usually more careful to distinguish the nationalities of the persons than the countries which they leave, or rather the countries from which they take their passage across the seas. In 1853 "foreigners" first began to be distinguished from British subjects in the returns of our emigration commissioners, and it may give some idea of the proportion in which the foreign element enters into the emigration of the United Kingdom to take a recent year. In 1874, for example, the emigrants who sailed from Britain are classified as follows: 116,490 English, 60,496 Irish, 20,286 Scotch, 38,465 foreigners, and 5277 "not distinguished." Yet considerable as the foreign element is in the United Kingdom statistics, its destination is small towards either our North American or Australasian colonies, and flows in the largest bulk to the United States, where the nationality of the immigrants is minutely discriminated in the returns of the emigration bureau. The table herewith given shows in decennial periods the main currents of European emigration and its principal destinations during the half century from 1820 to 1869 inclusive.

The "all other places," under which term statistics usually embrace the emigration not contained in the table, receive but a small though a growing portion of the persons who leave Europe with a view to industrial settlement elsewhere. There is the emigration to the River Plate, remarkable less for its amount than for the hold it possesses over the Latin races; and there is the emigration to the South African colonies, more promising of results in the future than can be gathered from its actual progress. In the Cape Colony and its various annexations there are 187,000 white or European settlers in a population of 776,000; and in the special colony of Natal only about one-seventh of the population are of European origin. The immigration to the River Plate in the six years 1868–73 was 250,698, of which in 1872 and 1873, when the immigration was largest, 56 per cent. were Italians, 19 Spaniards, 16 French, 3 British, 5 Germans, and 1 per cent. various, —the proportion of males being 73, and females 27.

The preference of emigration to British North America began to yield to the United States in the last five years of the decade 1830–39, when the politics of Canada were much disturbed; and other causes in the next decennial period gave an impulse in the same direction. But the effect of the potato famine of 1847 in Ireland on the course of emigration that ensued has probably been rated much beyond its due. It will be observed that the emigration of the Irish to the United States greatly exceeded that of English and Scotch in 1820–29, and was threefold greater in 1830–39 than it had been in 1820–29, while that of English and Scotch had much decreased. Taking into account these phenomena of the preceding twenty years, it is difficult to believe that more than 300,000 of the Irish emigration to the United States in 1840–49 can be accounted for by a failure of potato crops occurring in 1846–7. [1] It seems better, for more than simplicity's sake, to give the emigration from the United Kingdom to British North America and Australia, as here, in the gross. It had always more or less of a foreign element not easily separable in the returns from the English, Irish, and Scotch; and there has been a constant interchange of emigrants and immigrants between Canada and the United States, which complicates the matter still more. A surer test of the force of the respective emigrations up to the latest period is the number of alien-born inhabitants at the last census. In the Dominion of Canada at the census of 1871 there were 219,451 native-born Irish, 144,999 English and Welsh, 121,074 Scotch, 64,447 United States Americans, and 24,162 Germans. In the principal Australian colony—Victoria—at the census of the same year there were 164,287 native-born English, 6614 Welsh, 56,210 Scotch, 100,468 Irish, 8995 Germans, and nearly the same number of all other Europeans as of Germans.

that number of Irish displaced by the famine were absorbed in the industry of England and Scotland, of which the census returns since give abundant proof. If in the following decade, 1850–59, the Irish emigration to the United States rose to the enormous total of 1,073,065, it was accompanied by the no less surprising and much more sudden emigration of 935,171 Germans to the same quarter, pointing to more general causes than a local failure of crops, and showing how fruitfully the nations of the Old World may people the New with advantage to their social life, their trade, and their political stability, and to the general well-being. (R. SO.)

EMMAUS, a village to which, in the narrative of Luke, it is said two of the disciples of Jesus were journeying when he appeared to them on the day of his resurrection. The Authorized Version makes its distance from Jerusalem 60 furlongs, and although some manuscripts read 160, not only is the weight of authority in favor of the shorter distance, but it is impossible that the disciples, starting in the evening, could have walked the longer distance back to Jerusalem, and have still found the eleven gathered together. The only village of the name now remaining near Jerusalem is Emmaus Nicopolis, 20 miles distant, and from the 4th to the 14th century this village was believed to be the New Testament Emmaus. A tradition, which cannot be traced further back than the 14th century, fixes it at Kubeibeh; but except that the distance of Kubeibeh from Jerusalem corresponds with that of the village mentioned by Luke, no reason can now be discovered for the origin of the tradition. A place named Emmaus is mentioned by Josephus as distant from Jerusalem 60 furlongs; and he states also that the word Emmaus means "warm bath." The word is supposed to be the Greek form of the Hebrew word Hammath, which has the same meaning. Impressed with these considerations, Lieutenant Conder, R.N., in the *Quarterly Statement of the Palestine Exploration Fund* (October, 1876), suggests a site for the ancient Emmaus, "the most satisfactory yet proposed." He points out that Khamasa, the name of a ruin about 8 miles from Jerusalem, is probably an Arabic corruption of Hammath or Ammaus; and this opinion is corroborated by the fact that near the ruin are a spring of clear water and a little pool, with the remains of a small church. (See Zschokke, *Das neutestamentliche Emmaus*, 1865, and criticism by Menke in Petermann's *Mitth.*, 1866.)

EMMERICH (the ancient *Embrica*), a town of Prussia, in the government district of Düsseldorf, is situated on the right bank of the Rhine, and on the railway from Cologne to Amsterdam, 5 miles N.E. of Cleves. It has a considerable shipping trade, and manufactories of tobacco, chocolate, leather, liqueurs, ink, and perfumery. Its old minster church, built in the middle of the 11th century, contains some fine specimens of choir stalls. Emmerich was an important place at an early period, and seems in the middle of the 15th century to have contained 40,000 inhabitants. In 1794 it was bombarded by the French, and in 1806 it took the oath of allegiance to Murat. It passed into the possession of Prussia in 1815. The population in 1875 was 8117.

EMMET, ROBERT (1778–1803), brother of the subject of the next article, was born in Dublin in 1778. He was a schoolfellow of the poet Thomas Moore, and his senior by a year at Trinity College, Dublin. Both were members of the Historical Society, and the great champions of the popular side. In 1798 Emmet was expelled from the university on the ground of being connected with the association of United Irishmen. He shortly afterwards went to the Continent and remained there till 1802, when he returned secretly to Dublin, and endeavored to plan a general Irish revolution. On 23d July, 1802, deeming that the time had come to execute his scheme, he made an attempt to seize the arsenal and capital of Dublin; but the mob which he headed scarcely achieved so much as a serious riot, for they dispersed at the first military volley. Emmet fled to the Wicklow mountains, and perceiving that success was now impossible, resolved to escape to the Continent; but, contrary to the advice of his friends, he determined to have a last interview with the lady to whom he was attached, a daughter of Curran, the celebrated barrister. The delay proved fatal to him. He was apprehended, and committed for trial on the charge of high treason. He defended himself in a speech of remarkable eloquence, but was condemned to death, and on September 20, 1803, was executed in St. Thomas Street, Dublin. Moore, in one of the most pathetic of his Irish melodies, "Oh breathe not his name," commemorates Emmet's fate; and that of Miss Curran, who died in Sicily soon after him, is the subject of another, "She is far from the land where her young hero sleeps." Although it must be allowed that the conduct of Emmet in his revolutionary attempt was rash and mistaken, the high purity and unselfishness of his intentions have never been questioned.

A life of Emmet was written by the Countess of Haussonville, and was translated into English by John P. Leonard. See also *Life of Curran*, London, 1819; *Curran and his Contemporaries*, by C. Phillips, 1818; *Life of Robert Emmet*, by R. Madden, 1847; and *Robert Emmet, Cause of his Rebellion*, London, 1871.

EMMET, THOMAS ADDIS (1764–1827), a lawyer and politician, was born in Cork the 24th April, 1764. He was the second son of Dr. Robert Emmet, who latterly was state-physician in Dublin. After attending the school of Mr. Kerr in Cork, Thomas in 1778 entered Trinity College, Dublin. In 1783 he went to study medicine at the university of Edinburgh, where he continued four years. He then visited the chief medical schools of the Continent, and after travelling through Germany, France, and Italy, returned in 1788 to Ireland. Owing, he himself says, to the advice of Sir James Mackintosh, he now resolved to forsake medicine for law; and with the view of preparing himself for the Irish bar, he studied two years at the Temple, London. He was admitted a member of the Dublin bar in 1790. In the earlier years of his practice he was often engaged as counsel for those of the United Irishmen who were accused of political offences; but after he became more closely connected with the association, it was deemed prudent that, while privately acting as their legal adviser in all matters, he should no longer be engaged in the public defence of any of their number. In 1797 he became one of the directory of the association, and on the arrest of O'Connor about the middle of the same year, he succeeded him as chief leader. On the 12th March, 1798, he and other leaders were arrested, and after being examined at the castle were committed to Newgate. He was examined before a secret committee of the House of Lords, and afterwards before a secret committee of the House of Commons; and on the 9th April, 1799, he was conveyed as a prisoner to Fort George, Scotland, where he remained till June, 1802. He then received his liberty, but only on condition that he spent the remainder of his life on a foreign soil, his return to British territory being forbidden by severe penalties. After being conveyed to Cuxhaven, he proceeded to Hamburg, and finally to Brussels, where he passed the winter. In the beginning of 1803 he went to France, and had an interview with Napoleon; but having little faith in Napoleon's designs of invading England, he in the end of the year embarked for America. Here he rose to considerable eminence at the New York bar, and in 1812 held for a short time the office of attorney-general of the State of New York. He died suddenly, 14th November, 1827, while conducting a case in the United States circuit court.

See *Biography*, by C. S. Haynes, London, 1829; and memoir in Madden's *Lives of United Irishmen*, 2d vol. 2d ser., London, 1843.

EMMIUS, UBBO (1547–1626), a celebrated Dutch historian and geographer, was born at Gretha in East Friesland. He was chosen rector of the college of Norden in 1579, but was ejected in 1587 for refusing to subscribe the confession of Augsburg. He was subsequently rector of the colleges of Leer and Groningen, and when in 1614 the college in the latter city obtained a university charter, he was chosen as its principal and its professor of history and Greek, and by his wise guidance and his learning raised it speedily to a position of great eminence. He had correspondence with the principal learned men of his time, who all held him in high esteem. He died 9th December, 1626.

His principal works are—*Opus Chronologicum*, Gronin., 1619, fol.; *Vetus Græcia illustrata*, Leyd., 1626, 8vo.; *Rerum Frisicarum Historia*, Leyd., 1616, fol.; *Historia Temporis Nostri*, Gronin., 1732, 4to.

EMPEDOCLES, one of the most imposing and enigmatic figures in early Greek philosophy, was a native of

Agrigentum in Sicily, and lived in the 5th century, probably from 490 to 430 B.C. The details of his life are full of fable and contradictions. The most probable accounts represent him as belonging to an honorable family in the palmy days of his city, as a champion of free institutions, like his father Meton, detecting the aims of incipient tyrants, and crushing the opponents of popular rights, but as finally forced, through the change of parties that occurred during his visit to Olympia, to forego his native city, and to return to Peloponnesus to die. Of his poem on nature (*φύσις*) there are left about 400 lines in unequal fragments out of the original 5000; of the hymns of purification (*καθαρμοί*) less than 100 verses remain; of the other works, improbably assigned to him, nothing is known. His grand but obscure hexameters, after the example of Parmenides, delighted Lucretius. Aristotle, it is said, called him the father of rhetoric. But it was as at once statesman, prophet, physicist, physician, and reformer that he most impressed the popular imagination. To his contemporaries, as to himself, he seemed more than a mere man. The Sicilians honored his august aspect as he moved amongst them with purple robes and golden girdle, with long hair bound by a Delphic garland, and brazen sandals on his feet, and with a retinue of slaves behind him. Stories were told of the ingenuity and generosity by which he had made the marshes round Selinus salubrious, of the grotesque device by which he laid the winds that ruined the harvests of Agrigentum, and of the almost miraculous restoration to life of a woman who had long lain in a death-like trance. Legends stranger still told of his disappearance from among men. Empedocles, according to one story, was one midnight, after a feast held in his honor, called away in a blaze of glory to the gods; according to another, he had only thrown himself into the crater of Etna, in the hope that men, finding no traces of his end, would suppose him translated to heaven. But his hopes were cheated by the volcano, which cast forth his brazen sandals, and betrayed his secret.

As his history is uncertain, so his doctrines are hard to put together. He does not belong to any one definite school. While, on one hand, he combines much that had been suggested by Parmenides, Pythagoras, and the Ionic school, he has germs of truth that Plato and Aristotle afterwards developed. There are, according to Empedocles, four ultimate kinds of things, four primal divinities, of which are made all structures in the world—fire, air, water, earth. These four elements are eternally brought into union, and eternally parted from each other, by two divine beings or powers, love and hatred—an attractive and a repulsive force which the ordinary eye can see working amongst men, but which really pervade the whole world. According to the different proportions in which these four indestructible and unchangeable matters are combined with each other is the difference of the organic structure produced; *e.g.*, flesh and blood are made of equal parts of all four elements, whereas bones are one-half fire, one-fourth earth, and one-fourth water. It is in the aggregation and segregation of elements thus arising that Empedocles, like the atomists, finds the real process which corresponds to what is popularly termed growth, increase, or decrease. Nothing new comes or can come into being; the only change than can occur is a change in the juxtaposition of element with element.

Empedocles apparently regarded love and discord as alternately holding the empire over things,—neither, however, being ever quite absent. As the best and original state, he seems to have conceived a period when love was predominant, and all the elements formed one great sphere or globe. Since that period discord had gained more sway; and the actual world was full of contrasts and oppositions, due to the combined action of both principles. His theory attempted to explain the separation of elements, the formation of earth and sea, of sun and moon, of atmosphere. But the most interesting and most matured part of his views dealt with the first origin of plants and animals, and with the physiology of man. As the elements (his deities) entered into combinations, there appeared quaint results—heads without necks, arms without shoulders. Then as these fragmentary structures met, there were seen horned heads on human bodies, bodies of oxen with men's heads, and figures of double sex. But most of these products of natural forces disappeared as suddenly as they arose; only in those rare cases where the several parts were found adapted to each other, and casual member fitted into casual member, did the complex structures thus formed last. Thus from spontaneous aggregations of casual aggregates, which suited each other as if this had been intended, did the organic universe originally spring. Soon various influences reduced the creatures of double sex to a male and a female, and the world was replenished with organic life.

As man, animal, and plant are composed of the same elements in different proportions, there is an identity of nature in them all. They all have sense and understanding; in man, however, and especially in the blood at his heart, mind has its peculiar seat. But mind is always dependent upon the body, and varies with its changing constitution. Hence the precepts of morality are with Empedocles largely dietetic.

Knowledge is explained by the principle that the several elements in the things outside us are perceived by the corresponding elements in ourselves. We know only in so far as we have a cognate nature within us to the object of knowledge. Like is known by like. The whole body is full of pores, and hence respiration takes place over the whole frame. But in the organs of sense these pores are specially adapted to receive the effluxes which are continually rising from bodies around us; and in this way perception is somewhat obscurely explained.

It is not easy to harmonize these quasi-scientific theories with the theory of transmigration of souls which Empedocles seems to expound. Probably the doctrine that the divinity (*δαίμων*) passes from element to element, nowhere finding a home, is a mystical way of teaching the continued identity of the principles which are at the bottom of every phase of development from inorganic nature to man. At the top of the scale are the prophet and the physician, those who have best learned the secret of life; they are next to the divine. One law, an identity of elements, pervades all nature; existence is one from end to end; the plant and the animal are links in a chain where man is a link too; and even the distinction between male and female is transcended. The beasts are kindred with man; he who eats their flesh is not much better than a cannibal.

Looking at the opposition between these and the ordinary opinions, we are not surprised that Empedocles notes the limitation and narrowness of human perceptions. We see, he says, but a part, and fancy that we have grasped the whole. But the senses cannot lead to truth; thought and reflection must look at the thing on every side. It is the business of a philosopher, while he lays bare the fundamental difference of elements, to display the identity that subsists between what seem unconnected parts of the universe.

See Mullach, *Fragmenta Philosophorum Græcorum*, vol. i.; Zeller, *Phil. der Griechen*, Bd. i. (W. W.)

EMPEROR (*imperator*, *αὐτοκράτωρ*, *Kaiser*), a title formerly borne by the sovereigns of the Roman empire (see EMPIRE), and since their time by a variety of other potentates. The term *imperator* seems to have originally belonged to every Roman magistrate who received from the *comitia curiata* the *imperium* (*i.e.*, the power of the sword and authority to command in war). It was, therefore, in strictness not a title but a descriptive epithet. Towards the end of the Roman republic, however, it had become rather a special title of honor bestowed by the acclamations of a victorious army on their general, or by a vote of the senate as a reward for distinguished services (see Tac., *Ann.*, iii. 74; Cic., *Philipp.*, xiv. 4), and in this sense it continued to be used during the earlier period of the empire. Julius Cæsar, however, assumed it (under a vote of the senate) in a different sense, viz., as a permanent title, or rather as a part of his name (*prœnomen*), denoting the absolute military power which had come into his hands; and it was given by the senate, in like manner and with a like significance, to Augustus (see Dion Cassius, lii. 41, liii. 17.) Tiberius and Claudius refused it; but under their successors it soon became established as the regular official title of the monarch of the Roman world, ultimately superseding the name of *princeps*. When Greek became the sole language of the Eastern Roman empire, *imperator* was rendered sometimes by *βασιλεύς* and sometimes by *αὐτοκράτωρ*, the former word being the usual designation of a sovereign, the latter specially denoting that despotic power which the *imperator* held, and being in fact the official translation of *imperator*. Justinian uses *αὐτοκράτωρ* as his formal title, and *βασιλεύς* as the popular term. On the revival of the Roman empire in the West by Charles the Great in 800 A.D., the title (at first in the form *imperator*, or *imperator Augustus*, afterwards *Romanorum imperator Augustus*) was taken by him and by his Frankish, Italian, and German successors, heads of the Holy Roman Empire, down till the abdication of the emperor Francis II. in 1806. The doctrine had, however, grown up in the earlier Middle Ages (about the time of the emperor Henry II., 1002–1024) that although the emperor was chosen in Germany (at first by the nation, afterwards by a small body of electors), and entitled from the moment of his election to be crowned in Rome by the pope, he could not use the title of emperor until that coronation had actually taken place. The German sovereign, therefore, though he exercised, as soon as chosen, full imperial powers both in Germany and Italy, called himself merely "King of the Romans" (*Romanorum rex semper Augustus*) until he had received the sacred crown in the sacred city. In 1508 Maximilian I., being refused a passage to Rome by the Venetians, obtained from Pope Julius II. a bull permitting him to style himself emperor elect (*imperator electus*, erwählter Kaiser). This title was taken by Ferdinand I. (1558) and all succeeding emperors, immediately upon their coronation in Germany; and it was until 1806 their strict legal designation, and was always employed by them in proclamations and other official documents. The term "elect" was, however, omitted even in formal documents when the sovereign was addressed, or was spoken of in the third person.

According to mediæval theory, there was and could be only one emperor in the world, the direct vicegerent of God, who represented the unity of mankind and of the Christian people on its temporal side as the pope did on its spiritual. Hence during those ages the Western monarchs and Western writers did not admit in principle, though they sometimes recognized in fact, the title of the emperor who reigned at Constantinople; and the Easterns in like manner denied the existence of an emperor in the West, and maintained that the heads of the Holy Roman Empire were merely German intruders. In spite, however, of the universal acceptance of the theory above mentioned, the title of emperor was one which other princes seem to have hankered after. In 1053 Ferdinand the Great of Castile, in the pride of his victories over the Moors, assumed the style of *Hispaniæ imperator*, but was forced by the remonstrances of the emperor Henry III. to abandon it. In the 12th century it was again assumed by Alphonso VII. of Castile, but not by any of his successors. In England the Anglo-Saxon kings frequently used the term *basileus*, and sometimes also *imperator*, partly from a desire to imitate the pomp of the Byzantine court, partly in order to claim a sovereignty over the minor kingdoms and races of the British isles corresponding to that which the emperor was held to have over Europe generally (see Freeman, *Norman Conquest*, vol. i., Appendix, who however attaches too much importance to this English use).

In comparatively modern times, the title of emperor has been taken by the monarchs of Russia (Vassili, about 1520, his predecessors at Moscow having been called Great Dukes of Muscovy, and the title of Czar or Tsar being apparently a Slavonic word for prince, not related to Cæsar), France (Napoleon Bonaparte in 1804, Louis Napoleon Bonaparte in 1853), Austria (1805), Brazil (1822), Germany (December 31, 1870), Great Britain and Ireland in respect of the Indian dominions of the crown (1876). Usurpers who have reigned in Hayti, a certain Augustin Iturbide who (in 1822) became ruler of Mexico after the revolt against Spain, and the archduke Maximilian of Austria during his short tenure of power in Mexico, also called themselves emperors; and modern usage applies the term to various semi-civilized potentates, such as the sovereigns of China and Morocco. It can, therefore, hardly be said that the name has at present any definite descriptive force, such as it had in the Middle Ages, although its associations are chiefly with arbitrary military power, and it is vaguely supposed to imply a sort of precedence over kings. In the cases of Germany, Austria, and Britain in respect of India, it may perhaps be taken to denote that general over-lordship which their sovereigns exercise over minor princes and over their various territories, and which is distinct from their position as sovereigns of one or more particular kingdom or kingdoms, the German emperor being also king of Prussia, as the emperor of Austria is king of Hungry, and the empress of India queen of Great Britain and Ireland.

See Selden, *Titles of Honor*; Bryce, *Holy Roman Empire*; Sir E. Colebrooke, "On Imperial and other Titles," in the *Journal of the Royal Asiatic Society*, 1877. (J. BR.)

EMPHYSEMA (from ἐμφυσάω, to inflate), in medicine, means an abnormal presence of air in certain parts of the body. In its restricted sense, however, it is generally employed to designate a peculiar affection of the lungs, of which there are two forms. In one of these there is overdistension of the air-cells of these organs (see ANATOMY), and in parts destruction of their walls, giving rise to the formation of large sacs, from the rupture and running together of a number of contiguous air-vesicles. This is termed *vesicular emphysema*. In the other form the air is infiltrated into the connective tissue beneath the pleura and between the pulmonary air-cells, constituting what is known as *interlobular emphysema*.

The former variety is by far the more common, and appears to be capable of being produced by various causes, the chief of which are the following:—

1. Where a portion of the lung has become wasted, or its vesicular structure permanently obliterated by disease, without corresponding falling in of the chest wall, the neighboring air vesicles or some of them undergo dilatation to fill the vacuum.

2. In some cases of bronchitis, where numbers of the smaller bronchial tubes become obstructed, the air in the pulmonary vesicles remains imprisoned, the force of expiration being insufficient to expel it; while, on the other hand, the stronger force of inspiration being adequate to overcome the resistance, the air-cells tend to become more and more distended, and permanent alterations in their structure, including emphysema, are the result.

3. Emphysema also arises from exertion involving violent expiratory efforts, during which the glottis is constricted, as in paroxysms of coughing, in straining, and in lifting heavy weights. Hooping cough is well known as the exciting cause of emphysema in many persons.

In whatever manner produced, this disease gives rise to important morbid changes in the affected portions of the lungs, especially the loss of the natural elasticity of the air-cells, and likewise the destruction of many of the pulmonary capillary blood-vessels, and the diminution of aërating surface for the blood. As a consequence of these, other changes are apt to arise affecting related organs, more particularly the heart and the venous system generally, one of the most frequent results of which is the occurrence of dropsy. The chief symptom in this complaint is shortness of breathing, more or less constant but greatly aggravated by exertion, and by attacks of bronchitis, to which persons suffering from emphysema appear to be specially liable. The respiration is of similar character to that already described in the case of asthma. In severe forms of the disease the patient comes to acquire a peculiar puffy or bloated appearance, and the configuration of the chest is altered, assuming the character known as the *barrel-shaped* or *emphysematous thorax*.

The main element in the treatment of emphysema consists in attention to the general condition of the health, and in the avoidance of all causes likely to aggravate the disease or induce its complications. The same general plan of treatment as that recommended in asthma and bronchitis is applicable in emphysema. During attacks of urgent breathlessness antispasmodic remedies should be had recourse to, while the employment of dry cupping over the lungs, and even of moderate wet cupping over the precordium, will often afford marked and speedy relief.

Interlobular emphysema, arising from the rupture of air-cells in the immediate neighborhood of the pleura, may occur as a complication of the vesicular form, or separately as the result of some sudden expulsive effort, such as a fit of coughing, or, as has frequently happened, in parturition. Occasionally the air infiltrates the cellular tissue of the mediastinum, and thence comes to distend the integument of the whole surface of the body. When occurring suddenly and extensively, this has been known to produce death by asphyxia.

EMPIRE, a term used to denote either the territories governed by a person bearing the title of emperor (see Emperor), or, more generally, any extensive dominion. The historians of a former age were accustomed to enumerate a succession of great empires, and especially the Babylonian and Assyrian, the Medo-Persian, and the Macedonian, which had embraced the greater part of the civilized world before the rise of Roman power, but that system has now been abandoned. In its strict sense, "the Empire" meant during the Middle Ages, and indeed almost till the present century, the Romano-Germanic or so-called Holy Roman Empire, of which this is therefore the proper place to give a short account. The old Roman empire, founded by Julius Cæsar and Augustus, was finally divided in 395 A.D. between Arcadius and Honorius, the two sons of Theodosius the Great,—that is to say, one part of it, the Western, was ruled from Rome or Ravenna by one sovereign, and the other or Eastern half from Constantinople by another,—although the whole was still held to constitute, in theory, a single Roman state which had been divided merely for administrative purposes. In 476 the Western throne was overturned by Odoacer, the leader of an army of barbarian mercenaries in the imperial service; and the provinces which had obeyed it, so far as they were not then already occupied by invading German tribes, reverted to the emperor reigning at Constantinople, who thereby became again sole titular monarch of the Roman world. Justinian reconquered Italy in the following century, and his successors retained Rome, though Constantinople was their capital, for two centuries. This state of things lasted till 800, when Charles king of the Franks (Charlemagne) was crowned Roman emperor in Rome by Pope Leo III. All the Western provinces, except a part of Italy, had long since ceased to obey the emperor, and that part of Italy had rebelled about seventy years before. The object of the elevation of the Frankish king was to make Rome again the capital of an undivided Roman empire, rather than to effect a severance by creating a separate Western empire; but as the Eastern empire continued to subsist, the effect of the step really was to establish two mutually hostile lines of emperors, each claiming to be the one rightful successor of Augustus and Constantine, but neither able to dispossess its rival. The imperial title, which had fallen very low under the successors of Charles, was again revived in the West by Otto the Great, king of the East Franks, in 962; and from his time on there was an unbroken succession of German kings who took the name and enjoyed the titular rank and rights of Roman emperors, being acknowledged in the Western countries and by the Latin Church as the heads of the whole Christian community. Their power was, however, practically confined to Germany and Northern Italy, and after the death of Frederick II. (1250), it became comparatively weak even in those countries. In 1453 Constantinople was taken by the Turks, and the Eastern Roman empire came to an end. The Western, however, though now so feeble that it could only be kept on foot by choosing as emperor some prince powerful by his hereditary dominions, lasted on till the year 1806, when Francis II. of Hapsburg, archduke of Austria and king of Hungary and Bohemia, resigned his imperial title, and withdrew to the government of his hereditary kingdoms and principalities under the name (assumed the year before) of emperor of Austria. With him the Holy Roman Empire ended.

The territorial extent of the Romano-Germanic empire varied greatly at different periods of its history. In the time of Charles the Great it included the northern half of Italy (except the district about Venice), Gaul, Western and Southern Germany, and Spain between the Pyrenees and the Ebro. Under Otto the Great and his first successors it extended over the whole of Germany (including Holland and Belgium), as it then stood (modern Germany stretches further towards the north-east), and the south-east part of modern France, being what was then called the kingdom of Burgundy, and had claims of superiority, more or less definite in different cases, over the adjacent kingdoms of Hungary, Poland, and Denmark. Its further pretensions over the greater kingdoms of France, England, Spain, and Naples can hardly be said to have been admitted, though in a speculative sense the Holy Empire was held to include these states and indeed the whole Christian world. At the era of the Reformation all claims over districts outside Germany had become obsolete, nor were they ever revived. From the 15th century onwards it was practically conterminous with modern Germany, except that it did not include East Prussia.

The government of the Holy Roman Empire was never an absolute monarchy in the sense in which that of the old pagan empire had been, or that of the Eastern empire at Constantinople was while it lasted. Down till the end of the Hohenstaufen time (1254) it was a strong feudal monarchy, in which, as in the other feudal kingdoms of Europe, the sovereign enjoyed powers which were considerable but by no means unlimited, as he was obliged to respect the rights of his vassals, and could obtain supplies and pass laws only with the consent of the Diet, or supreme national assembly. From the time of Rudolf of Hapsburg (who came to the throne in 1272), its strength, which had been broken in a long struggle against the pope and the Italian republics, was much less; its revenues had shrunk, and the greater nobles had become practically independent princes, sovereign in their own territories, and sometimes stronger than the emperor. The struggles which attended and followed the Reformation still further weakened the authority of the crown, to which, as Roman Catholic, the Protestant princes and cities became almost of necessity hostile; and after the Thirty Years' War, when the Peace of Westphalia (1648) had finally settled the constitution of the empire, it was really no longer an empire at all, but a federation of very numerous principalities, some large, many very small, united under the presidency of a head who bore the title of emperor, but enjoyed scarcely any actual power, and represented in a Diet which was now not so much a national parliament as a standing congress of envoys and officials.

The imperial crown was always in theory elective, but in the earlier Middle Ages it was elective in much the same sense as the crowns of other feudal kingdoms, that is to say, the consent of the nobles and people, latterly of the chief nobles only, was required to the elevation of a sovereign, while practically it was hereditary, that is to say, the son or other near relative of the last sovereign was usually chosen to succeed him. Partly, however, owing to the extinction of several families in succession which had held it, partly to the influence of the pope and the idea that the imperial office was of a more sacred nature than the regal, the elective gradually came to prevail over the hereditary principle; and from the 13th century onwards, the Romano-Germanic throne was in the gift of a small electoral college consisting first of seven, then of eight, and ultimately of nine princes (see Pfeffinger, *Vitriarius illustratus;* Moser, *Römische Kayser;* Bryce, *Holy Roman Empire*). Nevertheless, from the election of Frederick III. in 1440 down to 1806, all the emperors except two—Charles VII. (1742) and Francis I. (1745)—belonged to the house of Hapsburg.

The present German empire, which came into existence when the king of Prussia accepted the title of emperor (December 31, 1870), is not legally a continuation of the Romano-Germanic empire, though practically it occupies a somewhat similar European position. Technically speaking, it is a new creation, which has not succeeded to the rights of Rome any more than the Russian empire has to those of the Eastern or Byzantine empire, which the czars have sometimes claimed to represent. (J. BR.)

EMPOLI, a town of Italy, in the province of Florence and district of San Miniato, is situated in a fertile plain on the river Arno, 6 miles from Florence, with which it is connected by railway. Its principal industries are the manufacture of cotton cloth, tanning, straw-plaiting, and the manufacture of macaroni. It has a collegiate church, founded in 1093, and containing some fine statuary and paintings by Giotto and others. The population in 1871 was 5949.

EMPYEMA (from ἐν, within, and πῦον, pus), a term in medicine applied to an accumulation of purulent fluid within the cavity of the pleura (see Pleurisy).

EMS, a watering place of Prussia, in the district of Wiesbaden, province of Hesse-Nassau, is situated on the Lahn, 7 miles S.E. of Coblentz, in a beautiful valley surrounded by wooded mountains and vine-clad hills. It possesses alkaline hot springs, which are used both for drinking and for bathing, and are considered of great efficacy as a remedy for chronic nervous diseases and affections of the liver and respiratory organs. About 15,000 persons frequent them annually. In Ems, on July 13th, 1870, took place the famous interview between King William of Prussia and

the French ambassador Benedetti, which resulted in the French and German war of 1870–71. The population of Ems in 1875 was 6104.

ENAMEL. An enamel may be best defined as a vitreous glaze fused to a metallic surface. There is indeed no difference between an enamel and a glaze, save in the character of the surface to which it is applied. Both are vitrified substances, either with or without color, and exhibiting every degree of translucency,—some varieties being perfectly transparent, while others are completely opaque. Chemically they consist of easily-fusible salts, such as the silicates and borates of sodium, potassium, and lead, to which various metallic oxides are added when it is desired to impart color to the enamel. These varieties of glass are pulverized, and the powder is used either in a dry or, more commonly, in a moistened state. The powder or paste, having been spread over the surface to be incrusted, is exposed to a moderate temperature in a muffle heated in the enamel-furnace, when the vitreous substance soon becomes sufficiently fluid to spread itself over the metallic surface, to which it closely adheres. If the glass is merely cemented to the metal, without any trace of fusion, the process is not true enamelling. Although it is extremely convenient to restrict the term "enamel," as in the definition at the head of this article, to those glassy materials which are applied to the surface of metals, it should be remarked that some writers extend it to glazes which are employed on pottery and on other non-metallic materials; while popularly the term has a yet wider use, being applied, in fact, to almost any brilliant surface, whether produced by varnishing, by lacquering, or by other processes not involving fusion; hence we hear of enamelled leather, enamelled paper, enamelled slate, etc. Sometimes a coating of true enamel or of glaze is employed solely for utility, as in the case of vessels of enamelled iron or of glazed earthenware; but more commonly enamels are applied with a view to decorative effect, the decoration thus produced being extremely permanent, since the fused material is but little affected by atmospheric influences. When enamelling is thus artistically employed, it is usual to speak of the finished works of art themselves as "enamels;" and as such usage has no practical inconvenience, it will be followed in this article.

According to some authorities, the oldest reference to enamelling is to be found in the book of Ezekiel (i. 4, 27; viii. 2). The original word *chashmal*, חַשְׁמַל, was translated by the LXX. ἤλεκτρον, and appears in the authorized version as *amber*. Gesenius, however, believes that the Hebrew word signified polished metal rather than amber. Pliny tells us that the word *electrum* was applied to two distinct substances, namely, to amber and to an alloy of $\frac{4}{5}$ gold and $\frac{1}{5}$ silver. It has been held, however, by M. Labarte, a great authority on the history of enamelling, that there are passages in Homer and in Hesiod in which the word *electron* will not bear either of Pliny's meanings, but must be taken to signify enamelled gold. Labarte has found a formidable opponent to this interpretation in the Count Ferdinand de Lasteyrie (*L'Électrum des anciens était-il de l'émail?* Paris, 1857).

To whatever period the origin of enamelling may be assigned, it is certain that glazes having the composition of good enamels were manufactured at a very early date. Excellent glazes are still preserved on some of the bricks which have been found among the ruins of Babylonia and Assyria, and have been referred to the 8th or 7th century B.C. Nor should we forget the glazed slipper-shaped coffins which occur in great numbers at Warka, probably the ancient Ur of the Chaldees, and are referred to the Sassanian period. The glazes on the Babylonian bricks were examined by Dr. Percy, who found that the base was a soda-glass, or silicate of sodium, rendered opaque in some specimens by the presence of stannic oxide, or colored blue in others by means of silicate of copper associated with the sodic silicate, or exhibiting in other specimens a fine yellow color, due to the presence of antimony and lead, probably in the form of "Naples yellow." Glazes, of a similar character to some of these, were also manufactured by the Egyptians as early as the sixth dynasty. Sepulchral figures, and a variety of other objects familiar to students of Egyptian art, were produced in a substance which has been miscalled "porcelain," and which is, in fact, a frit coated with variously-colored glazes, of which the most common is of a fine celestial blue color. This color is due to the presence of a double silicate of copper and sodium. Beautiful as these glazes unquestionably are, they are not true enamels, since they are not applied to metallic surfaces. It is true that the ancient Egyptians were able to produce an effect not unlike that of enamelling by inlaying bronze and gold with colored pastes. But Dr. Birch says of the Egyptians that "their real enamelling does not appear to be older than the time of the Ptolemaic and Roman dominion in Egypt."

There can be little doubt that the Greeks and Etruscans were acquainted with the art of enamelling. They seem, however, to have practised it to only a very limited extent, and it may be fairly doubted whether they had attained to such a mastery of its details as some writers have assumed. Thus M. Lenormant, writing in 1863, says—

> "Les collections de l'Europe prossédent maintenant des pièces incontestables qui démontrent pour les Égyptièns, les Phéniciens, les Grecs, et les Etrusques, la connaissance des secrets les plus difficiles de l'émaillerie, ainsi que la pratique de toutes les formes et de toutes les applications dont ce procédé peut être susceptible."

Whatever knowledge of enamelling the Greeks may at one time have possessed, they appear to have lost it before the 3d century of our era. This is inferred from a famous passage in Philostratus, which was probably written about 240 A.D. Philostratus was a Greek sophist who went from Athens to the court of Julia, the wife of Septimius Severus. The passage is found in the *Icones* (lib. i. cap. 28), and since attention was first called to it by Buonarroti, it has been quoted by all writers on enamelling; it is, in fact, the earliest distinct reference to the art. "It is said that the barbarians who inhabit the ocean pour these colors," alluding to the colored decorations of some horse-trappings, "on to heated bronze, and that they adhere, become as hard as stone, and preserve the designs."[1] On this passage the learned commentator Olearius remarks, "Celtas intelligit per barbaros in Oceano." It is a vexed question, however, whether the reference applies to the Celts of Britain or to those of Gaul. French writers naturally apply the allusion to the maritime Gauls; but Mr. Franks and some others have pointed out that the expression used by Philostratus, ἐν Ὠκεανῷ, would refer more appropriately to an insular people, like the Britons. Large numbers of enamelled objects have indeed been found in various parts of England, Scotland, and Ireland. Among these ornamental objects are shields, fibulæ, rings, and even bits and other horse-furniture, such as are probably referred to in the passage from the *Icones*. The ornamentation is mostly in that style which has been designated by Mr. Franks as late Celtic. Excellent examples are furnished by the enamels which were found in the Victoria Cave near Settle in Yorkshire, and have been described by Professor Boyd Dawkins; these are referred to about the 5th century. (See article CAVE, vol.

---

[1] Ταυτά φασι τὰ χρώματα τοὺς ἐν Ὠκεανῷ βαρβάρους ἐγχεῖν τῷ χαλκῷ διαπύρῳ, τὰ δὲ συνίστασθαι καὶ λιθοῦσθαι, και σώξειν ἅ εγράφη.

v., p. 235.) It is not improbable that the art of enamelling, after it ceased to be cultivated in Britain, may have lingered in Ireland, which is known to have been a great centre of arts and sciences during the 6th and 7th centuries.

Although such specimens as those just referred to seem to show that enamelling was practised at a very early period in Western Europe, it is nevertheless in the Eastern empire that we find the earliest historic evidence of the art having flourished as an important industry. Byzantium was indeed for centuries the great seat of this industry, which probably dated from at least the time of Justinian. The word *smaltum* is found for the first time in a life of Leo IV. written in the 9th century. Theophilus, the artist-monk, has left a minute description of the manner in which the Byzantine enamellers of the 10th century carried on their work. Most of the Byzantize enamels were executed on plates of gold, and large numbers have no doubt been destroyed on account of the intrinsic value of the metal. Such specimens as are extant furnish valuable examples of what is known as the *cloisonné* process.

In cloisonné work, the design is presented in colored enamels which are separated one from another by means of ribs of metal bent so as to follow the outline of the subject. A plate of gold generally formed the basement of the work, and upon this plate the design was traced in slender fillets of gold. These threads were easily bent to the required form, and were fixed upright upon the plaque, so as to form a number of cells for reception of the enamel. The powdered glass, moistened into a paste, was carefully introduced into these compartments, and the prepared plate was then fired. To retain the fused enamel, the edges of the plates were slightly turned up, thus forming a rim. After careful cooling, the irregular fused surface was ground down, and polished, when the design appeared in colored enamels separated by gold partitions, or *cloisons*. In many cases the metal base forms part of the field, and the subject is then enamelled in a hollow which has been beaten out, while the gold forms a brilliant background. Cloisonné enamelling has been employed by the Chinese and Japanese, who, instead of restricting it to flat surfaces of the precious metals, have applied it to copper vases and other large hollow vessels. They also ingeniously attach the metal fillets to the surface of pottery, and thus produce cups, vases, and other objects in porcelain ornamented with cloisonné work. Many Chinese and Japanese enamels are, however, executed by other processes, such as the champ-levé and surface methods, to be afterwards described.

The most famous example of Byzantine cloisonné work is the Pala d'Ora at St. Mark's, Venice. This magnificent altar-piece contains a number of enamelled panels and medallions, executed for the most part on gold, though some are on silver. It is believed that the Pala was brought from Constantinople to Venice about the year 1105, and that some of the enamels may be referred to this date; but probably they are not all of the same period. Among other interesting examples of ancient cloisonné enamelling, reference may be made to the well-known Alfred Jewel, which was found at Athelney in Somersetshire in 1693, and is preserved in the Ashmolean Museum at Oxford. The face of the jewel is of rock-crystal, beneath which is a figure-subject in semi-transparent enamels of blue, white, green, and brown. Around the edge is the legend, ÆLFRED MEC HEHT GEVVRCAN (Alfred ordered me to be made). Possibly this jewel, or at least the enamelled part, was brought from the East, and is not an example of Saxon enamelling. Cloisonné work is also seen in the cross which was obtained from the tomb of Queen Dagmar, who died in 1213, in a valuable pectoral cross belonging to Mr. A. J. Beresford Hope, and in a small portrait of St. Paul on gold, in the Museum of Practical Geology, London.

A rare variety of cloisonné enamelling is known to French antiquaries as enamel "de plique à jour." The peculiarity of this style consisted in setting transparent enamels without any background, so that light could be freely transmitted through the glass, the enamels being fixed by having their edges fused to the windows in which they were framed. Specimens of this work are extremely rare. A fine example, in the shape of a small covered cup, may be seen in the South Kensington Museum, having been purchased for the sum of £400.

Very similar in effect to the cloisonné enamels, but much less rare and valuable, are those inlaid works which were executed by the *champ-levé* process. Copper was usually employed in place of the precious metals; and the partitions between one color and another were formed by ridges of the base and not by separate fillets of metal. A plate of copper, about ¼ inch thick, and having the surface polished, formed the ground-work of the enamel. By means of a graver, the parts to be enamelled were chased out, so as to leave slender ribs standing up as boundary-walls to the cavities. Enamel in the state of either powder or paste was then introduced into these casements, and the work was fired. Finally, the surface was polished, and the metallic outlines generally gilt. In some examples, the figures are represented in enamel on a metal background; while in others the figures stand out in engraved metal upon an enamelled background; and in others again the entire field is enamelled.

Champ-levé enamelling was applied to a vast variety of purposes, and specimens of the work are to be found in almost every museum. The late Celtic or Romano-British enamels, referred to above, belong to this class. One of the most interesting champ-levé enamels of early date is the elegant bronze vase which was found in 1835 in a tumulus at Bartlow, in the parish of Ashdown, Essex. The sepulchral mound formed one of a group of four conical barrows, which have been referred by their contents to the late Roman period. The vase is a globular vessel with rectangular handle, ornamented with bands of running leaves and flowers executed in blue, green, and red enamels. Faraday showed that the blue color was due to cobalt, and the red to copper, the green also being probably a copper-color. This singularly interesting specimen suffered from a fire at Easton Hall in 1847, and its remains are now in the British Museum. (See colored figure in *Archæologia*, vol. xxvi.) Another famous example of this kind of enamelling is seen in Westminster Abbey, in the tomb of William de Valence, earl of Pembroke, who died in 1296. It is highly probable that the enamels on this monument were executed at Limoges in France, a city which during the Middle Ages was the chief centre of the enamelling industry. So numerous were the enamels of the early Limoges school that it is impossible within the limits of this article to refer to special examples. They date back certainly as early as the latter part of the 12th century; for a letter which is referred to the year 1170 alludes to an enamelled book-cover *de opere Lenovicino*. The champ-levé process was extensively applied by the Limoges enamellers to the decoration of altar-furniture, especially reliquaries or shrines, pyxes for preserving the host, priket candlesticks, ciboria, crosiers, and other ecclesiastical appointments. During the 14th century Limoges lost its reputation; but it revived at a later period in an entirely new style of enamelling. The inlaid process, in fact, gave way to that of painted enamels, and the graver was displaced by the pencil. But before noticing the process of superficial enamelling, it is desirable to refer to another style, which took its birth in Italy at the beginning of the 14th century.

In the Italian process, the enamels were always more or less translucent, and completely covered the metal ground, the design being defined by sculpturing beneath the transparent medium. The enamels were of various colors, and differences of shade were obtained by the varying thickness of the glass in different parts of the design. Gold or silver was the metal generally employed. The subject was chased in very low relief, and covered with powdered enamels. Great care was required during firing, to prevent the several colors running together in a confused mass. As examples of translucent enamels, reference may be made to the silver horn, known as the "Bruce horn," the property of the marquis of Aylesbury, and to the crosier of William of Wykeham at New College, Oxford.

Soon after the introduction of transparent enamelling in Italy, the art became popular in France, and this probably led the way to the invention of *enamel-painting*. The artists of Limoges acquired great celebrity in this work. The early painted enamels from the Limousin workshops were executed in opaque white upon a brown ground, the white being overlaid where necessary by transparent colored enamels. The lights were picked out in gold, while the brilliant effect of gems was obtained by the use of *paillettes*, or colored foils. Nardon Pénicaud is the best known artist in this style, and an excellent example of his work, dated 1503, is preserved in the Hôtel de Cluny in Paris.

About the beginning of the 16th century a much more finished style of painting was introduced at Limoges; and under the auspices of Francis I. the art attained to a considerable development. Léonard Limousin, who is known to have painted from 1532 to 1574, became the great master of this style. While some of the works were executed in brilliant colors, most of them were in monochrome. The background was generally dark, either black or deep purple, and the design was painted *en grisaille*, relieved in the case of figure-subjects by delicate carnations. The effect was occasionally heightened by appropriate touches of gold, and in many of the colored enamels brilliancy was obtained by the use of silver foil, or *paillon*, placed beneath a transparent enamel. Portraits were frequently painted on copper plaques; and the art was also applied to the decoration of ewers, vases, plateaux, candlesticks, salt-cellars, and a variety of elegant objects for domestic as well as ecclesiastical use. Among the artists of this school may be mentioned Pierre Raymond, Jean Pénicaud, Pierre and Jean Courtois, Martin Didier, Jean Court dit Vigier, P. Courteys, and the master known only by his initials C. N.

Towards the latter end of the 16th and in the beginning of the 17th century it was the fashion for the Limoges enamellers to paint in a minute style, which is seen in the works of the brothers Laudin and of the family of Nouailhers. The art at length degenerated into a system of tawdry coloring, and in the reign of Louis XIV. it fell into a state of decay, from which an attempt to revive it was made by Louis XVI., but without success.

Probably the decline of the Limoges school was connected with the rise of a new branch of enamelling, which has been distinguished as the *miniature style*. This is the style which has continued in vogue up to the present day. Its invention is ascribed to Jean Toutin, a goldsmith of Châteaudun, but it was greatly improved by Jean Petitot of Geneva, who carried it to a high state of perfection, and painted for Charles I. in England and for Louis XIV. in France. These enamels are executed generally on plates of copper or of gold, but silver is sometimes employed. In consequence of the risk involved in the successive firings, the plates were formerly confined to a small size, about 5 or 6 inches square. Horace Hone, an English enameller of the last century, was the first who attempted large pieces, but he was excelled by Henry Bone, R. A. Bone had been a china painter in the Plymouth and Bristol works; and on his removal to London he applied his knowledge of vitrified pigments to enamel painting. Excelling all his predecessors in the magnitude of his plates, he ventured on subjects so large that in 1810 he painted a noble plaque measuring 18 inches by 16 inches. This master-piece was a copy of Titian's famous Bacchus and Ariadne, in the National Gallery, and was purchased by Mr. Bowles of Wanstead for 2200 guineas. Bone's chief works were a series of portraits of celebrities of the Elizabethan period, which were sold by auction on the artist's death in 1834. (See BONE, vol. iv. p. 29.) Enamelling was also prosecuted by his son, H. P. Bone, who executed a very large Madonna and Child, and by his grandsons, W. Bone and C. R. Bone, both of whom are recently deceased. The art of enamel painting was also carried on by A. Essex, but of late years it has not been extensively cultivated in this country. In connection with remarkable enamels it should be mentioned that a painting of the Holy Family, after Parmigiano, was executed by C. Muss on a plaque measuring as much as 20 inches by 15 inches. This noble work was purchased by George IV. for 1500 guineas.

In order to prepare a plate for the artist, a thin piece of gold or of copper is carefully annealed, and then coated with a dead white enamel. The enamel is imported in cakes from Venice, and is made from a mixture of silica, borax, and stannic oxide. After the plate has been fired, a second coating of enamel is applied, and the plate returned to the oven. It is afterwards coated for the third time, but now with a more easily fusible glass, which is known in the workshop as "flux." This is also imported from Venice, in the form of tubes and beads, and is employed to produce a brilliant lustre on the surface. The ground having been thus prepared is carefully ground smooth, and is then ready for the artist. The colors which he employs consist of various metallic oxides mixed with the flux; but it is obvious that the enameller's palette must be limited, since he is able to employ only such substances as are permanent at the temperature to which the plate will be subjected in the muffle. Blue colors are produced by means of oxide of cobalt; violet by oxide of manganese; green by cupric oxide or by chromic oxide; red either by cuprous oxide, which is difficult to work in the oven, or by the preparation of gold known as purple of Cassius, which also produces a fine purple; yellow by oxide of silver, oxide of lead, or an alkaline antimoniate; brown by ferric oxide; and black by ferrous oxide, or by means of cobalt and manganese, which have intense tinctorial power, and produce dense colors. Special recipes will be found in technical treatises, and need not be inserted here.

The powdered colors of the enameller are mixed with oil of lavender or spike and spirit of turpentine, as a vehicle, and are applied to the enamel-ground by means of a camel's-hair pencil. After each layer has been spread over the surface, the plate must be fired, and highly-finished work may have to pass through the oven a score of times. Once vitrified, the colors are permanent; hence the artist has no opportunity of correcting faults, except by the tedious process of grinding away a portion of the plate. Since the tints may be greatly modified by too high a temperature, the greatest care is needed in managing the furnace. In return for the great labor and risk involved in enamelling, the artist secures permanence for his work, the painting being always as fresh as when first executed; it is indeed a painting in glass.

In the middle of the last century the art of enamelling was largely applied to the decoration of snuff-boxes, patch-boxes, tea-canisters, candlesticks, needle-cases, labels for wine-bottles, and a variety of other small articles. The manufacture was established by Mr. S. T. Janssen at York House, Battersea, near London, about the year 1750. The objects were usually made of copper; and having been coated with an opaque white enamel, were decorated with Watteau subjects and floral and other designs, painted in enamel colors. A peculiar rose-tint was a favorite color at Battersea. Advantage was also taken of the process of transferring engravings from copper-plates to glazed surfaces—a process which was introduced about the year 1750 by Sadler and Green of Liverpool, and was largely employed for the decoration of pottery and porcelain. It is known that a manufacturer of small enamelled objects, similar to those made at Battersea, but usually decorated in coarser style, was carried on by George Brett at Bilston in South Staffordshire. Splendid snuff-booxes and other ornamental articles in enamelled work were also turned out by artists in France and Germany.

Of late years the art of enamelling has been extensively applied to the coating of iron vessels for domestic purposes, with the view of keeping a clean surface and preventing the rusting of the metal. As far back as 1799, a process for this kind of enamelling was introduced by Dr. Hickling; and within the last thirty years a large number of patents have been granted for similar purposes. One of the most extensively used processes is that of Charles Henry Paris, which was introduced into England in 1850, and is now largely worked at Birmingham. The metal articles are first cleaned with dilute sulphuric acid, and powdered glaze is then sifted upon the clean surface. Adhesion of the powder is secured by applying to the iron a coating of gum-water. The object is then dried in an oven, whence it is transferred to the enamelling-furnace, where it is heated until the fused glaze flows evenly over the surface. After removal from the oven, the objects are allowed to cool with extreme slowness. It is often found necessary to apply a second coating of enamel. Paris's composition consists of 130 parts of cullet or broken glass, 20½ parts of carbonate of sodium, and 12 parts of boracic acid. This forms the fundamental glaze, upon which variously colored enamels may be employed. If enamelled vessels are to be used for culinary purposes, great care must be taken that the glass contains no lead, the presence of which would be highly dangerous. Acids often find their way through the pores of an enamel to the subjacent metal, and spreading out between the iron and the glaze, cause the enamel to peel off. Exposure to sudden changes of temperature also tends to injure the enamel.

Enamelling of a similar character is now largely used for street plates, name-plates at railway stations, advertising tablets, and other objects where permanent lettering is required. The insides of baths, cisterns, and boilers are also protected by enamelling; and it has been proposed to prevent the fouling of ships' bottoms by a coating of enamel. In 1871 a patent was granted to Mr. Neilson of Glasgow for enamelling large metal objects, to which the process had not been previously applied, and also for improvements in the mechanical appliances needed for the transference of large objects in and out of the enamelling oven.

For the history of enamelling see M. Labarte's *Recherches sur la Peinture en Émail* (Paris, 1856). This is incorporated in the author's *Histoire des Arts industriels au Moyen Âge* (vol. iii. 2d. ed. Paris, 1875). See also, the Marquis de Laborde's *Notice des Émaux exposés dans les galeries du Musée du Louvre* (Paris, 1852). English readers will find an admirable sketch of the history in Mr. Franks's *Observations on Glass and Enamel*, extracted from the *Art Treasures of the U. K.* For details of old processes the works of Neri and Benvenuto Cellini may be consulted. Valuable papers will be found in the *Archæolog. Journ.* (vol. ii. p. 154), by Albert Way; *Journ. Arch. Assoc.* (vol. iii: p. 280), by W. H. Rogers; and *Art Journal* for 1851, by A. Essex. The following works are also deserving of notice—M. Reboulleau's *Noveau Manuel complet de la peinture en verre sur porcelaine et sur émail* (new ed., by M. Magnier, Paris, 1866), and M. Claudius Popelin's *L'Émail des Peintres* (Paris, 1866). (F. W. R.*)

ENCAUSTIC PAINTING. The name *encaustic* is applied to paintings executed with vehicles in which wax is the chief ingredient. The term was appropriately applied to the ancient methods of painting in wax, because these required heat to effect them. Wax, however, may now be used as a vehicle for painting without heat being requisite; nevertheless the ancient term *encaustic* has been retained, and is indiscriminately applied to all methods of painting in wax. The durability of wax, and its power of resisting the effects of the atmosphere, were well known to the Greeks, who used it for the protection of their sculptures. As a vehicle for painting it was commonly employed by them and by the Romans and Egyptians; but in recent times it has met with only a limited application. Of modern encaustic paintings those by Schnorr in the Residenz at Munich are the most important. At present there is no general agreement as to which is the best method of using wax for mural painting. Modern paintings in wax, in their chromatic range and in their general effect, occupy a middle place between those executed in oil and in fresco. Wax painting is not so easy as oil, but presents fewer technical difficulties than fresco.

Ancient authors often make mention of *encaustic*, which, if it had been described by the word *inurere*, to burn in, one might have supposed to have been a species of enamel painting. But the expressions "incausto pingere," "pictura encaustica," "ceris pingere," "pictura inurere," used by Pliny and other ancient writers, make it clear that some other species of painting is meant. Pliny distinguishes three species of encaustic painting. In the first they used a stylus, and painted either on ivory or on polished wood, previously saturated with some certain color; the point of the stylus or stigma served for this operation, and its broad or blade end cleared off the small filaments which arose from the outlines made by the stylus in the wax preparation. In the second method it appears that the wax colors, being prepared beforehand, and formed into small cylinders for use, were smoothly spread by the spatula after the outlines were determined, and thus the picture was proceeded with and finished. By the side of the painter stood a brazier, which was used to heat the spatula and probably the prepared colors. This is the method which was probably used by the painters who decorated the houses of Herculaneum and of Pompeii, as artists practising this method of painting are depicted in the decorations. This method has recently been revived in Italy. The third method was by painting by a brush dipped into wax liquefied by heat; the colors so applied attained considerable hardness, and could not be damaged either by the heat of the sun or by the effects of sea-water. It was thus that ships were decorated; and this kind of encaustic was therefore styled "ship painting."

About the year 1749 Count Caylus, and M. Bachelier, a painter, made some experiments in encaustic painting, and the count undertook to explain an obscure passage in Pliny, supposed to be the following (xxxv. 39):—"Ceris pingere ac picturam inurere quis primus excogitaverit non constat. Quidam Aristidis inventum putant, postea consummatum a Praxitele; sed aliquanto vetustiores encausticæ picturæ extitere, ut Polygnoti et Nicanoris et Arcesilai Pariorum. Lysippus quoque Æginæ picturæ suæ inscripsit *ἐνέκαυσεν*, quod profecto non fecisset nisi encaustica inventa." There are other passages in Pliny bearing upon this subject, in one of which (xxi. 49) he gives an account of the preparation of "Punica cera." The nature of this Punic wax, which was the essential ingredient of the ancient painting in encaustic, has not been definitely ascertained. The Chevalier Lorgna, who investigated the subject in a small but valuable tract, asserts that the *nitron* which Pliny mentions is not the nitre of the moderns, but the *natron* of the ancients, viz., the native salt which is found crystallized in Egypt and other hot countries in sands surrounding lakes of salt water. This substance the Carthaginians, according to Pliny, used in preparing their wax, and hence the name Punic seems to be derived. Lorgna made a number of experiments with this salt, using from three to twenty parts of white melted wax with one of natron. He held the mixture in an iron vessel over a slow fire, stirring it gently with a wooden spatula, till the mass assumed the consistency of butter and the color of milk. He then removed it from the fire, and put it in the shade in the open air to harden. The wax being cooled liquefied in water, and a milky emulsion resulted from it like that which could be made with the best Venetian soap.

Experiments, it is said, were made with this wax in painting in encaustic in the apartments of the Count Giovanni Battista Gasola by the Italian painter Antonio Paccheri, who dissolved the Punic wax when it was not so much hardened as to require to be "igni resoluta," as expressed by Pliny, with pure water slightly infused with gum-arabic, instead of sarcocolla, mentioned by Pliny. He afterwards mixed the colors with this wax so liquefied as he would have done with oil, and proceeded to paint in the same manner; nor were the colors seen to run or alter in the least; and the mixture was so flexible that the pencil ran smoother than it would have done with oil. The painting being dry, he treated it with caustic, and rubbed it with linen cloths, by which the colors acquired peculiar vivacity and brightness.

About the year 1755 further experiments were made by Count Caylus and several French artists. One method was to melt wax with oil of turpentine as a vehicle for the colors. It is well known that wax may be dissolved in spirit and used as a medium, but it dries too quickly to allow of perfect blending, and would by the evaporation of the spirit be prejudicial to the artist's health. Another method suggested about this time, and one which seems to tally very well with Pliny's description, is the following. Melt the wax with strong solution of salt of tartar, and let the colors be ground up in it. Place the picture when finished before the fire till by degrees the wax melts, swells, and is bloated up upon the picture; the picture is then gradually removed from the fire, and the colors, without being injuriously affected by the operation of the fire, become unalterable, spirits of wine having been burnt upon them without doing the least harm. Count Caylus's method was different and much simpler: (1) the cloth or wood designed for the picture is waxed over, by rubbing it simply with a piece of beeswax; (2) the colors are mixed up with pure water; but as these colors will not adhere to the wax the whole ground must be rubbed over with chalk or whiting before the color is applied; and (3) when the picture is dry it is put near the fire, whereby the wax is melted and absorbs the colors. It must be allowed that nothing could well be simpler than this process, and it was thought that this kind of painting would be capable of withstanding the weather and of lasting longer than oil painting. This kind of painting has not the gloss of oil painting, so that the picture may be seen in any light, a quality of the very first importance in all methods of mural painting. The colors too, when so secured, are firm, and will bear washing, and have a property which is perhaps more important still, viz., that exposure to smoke and foul vapors merely leaves a deposit on the surface without injuring the work. The "encausto pingendi" of the ancients could not have been enamelling, as the word "inurere," taken in its rigorous sense, might at first lead one to suppose, nor could it have been painting produced in the same manner as encaustic tiles or encaustic tesseræ; but that it must have been something akin to the count's process would appear from the words of Pliny already quoted, "Ceris pingere ac picturam inurere."

Werner of Neustadt found the following process very effectual in making wax soluble in water. For each pound of white wax he took twenty-four ounces of potash, which he dissolved in two pints of water, warming it gently. In this ley he boiled the wax, cut into little bits, for half an hour, after which he removed it from the fire and allowed it to cool. The wax floated on the surface of the liquor in the form of a white saponaceous matter; and this being triturated with water produced a sort of emulsion, which he called wax milk, or encaustic wax. This preparation may be mixed with all kinds of colors, and consequently can be applied in a single operation.

Mrs. Hooker of Rottingdean made, at the end of the last century, many experiments to establish a method of painting in wax, and received a gold palette from the Society of Arts for her investigations in this branch of art. Her account is printed in the tenth volume of the Society's Transactions (1792), under the name of Miss Emma Jane Greenland. The following is an abstract of her processes:—

Put into a glazed earthen vessel four ounces and a half of gum arabic, and eight ounces or half a pint wine measure of cold spring water; when the gum is dissolved, stir in, over a low fire, seven ounces of gum mastic, continually stirring and beating hard with a spoon, in order to dissolve the gum mastic. When sufficiently boiled the mixture will no longer appear transparent, but will become opaque and stiff like a paste. As soon as this is the case, and the gum water and mastic are quite boiling, without taking them off the fire, add five ounces of white wax, broken into small pieces; stir and beat till the wax is perfectly melted and boils; then take the composition off the fire, as boiling it longer than necessary would harden the wax, and prevent it afterwards from mixing well with water. When the composition is taken off the fire, it should be beaten well whilst hot (but not boiling) in the glazed earthen vessel; mix with it by degrees a pint or sixteen ounces more of cold spring water, then strain the composition, and bottle it. The composition if properly made should be like cream, and the colors when mixed with it as smooth as with oil. Mix with the composition on a china palette any powder colors which may be required to the consistency of oil colors; then paint with pure water. In painting with this composition the colors blend without difficulty when wet, and even when dry the tints may be easily united by means of a brush and a very small quantity of water. The painting being finished, heat some white wax in a glazed earthen vessel over a slow fire till melted, but not boiling; then with a hard brush cover the painting with the wax; when cold take a moderately hot iron, such as is used for ironing linen, and which will not "hiss" when put to the usual test, and draw it lightly over the wax. The painting will appear as if under a cloud, till the wax and the substance the picture is painted upon are perfectly cold; but if then it should not appear sufficiently clear, the wax may be melted by holding a hot iron at a proper distance from it, especially before such portions of the picture as do not appear sufficiently transparent or brilliant; for the oftener heat is applied to the picture the greater will be the transparency and the brilliancy of the coloring; but the contrary effect would be the result were the heat applied too suddenly, in too great a degree, or for too long a time. When the picture is cold, rub it with a fine linen cloth. Plaster surfaces require no other preparation than a coating of the composition.

It would be equally practicable to paint with wax alone dissolved in gum water. Take three quarters of a pint of cold spring water, and four ounces and a half of gum arabic, put them into a glazed earthen vessel, and when the gum is dissolved, add eight ounces of white wax. Put the earthen vessel, with the gum water and wax, upon a slow fire, and stir them till the wax is dissolved, and when the mixture has boiled a few minutes, take it off the fire, and throw it into a basin, as by remaining in the hot earthen vessel the wax would become rather hard; beat the gum water and wax till quite cold. It is necessary to use some pure water in mixing this composition with the colors. If the ingredients should separate when bottled, they have only to be well shaken together. This composition may be kept for a long time, and be rendered fit for use by putting a little cold water upon it for a short time.

The following is a recent recipe. Place in a large pipkin, half full of hot turpentine, as much gum dammar as will dissolve (½ ℔ gum makes about 1½ pints varnish); melt from two to two and a half of the wax tablets sold by chemists in a pint of this varnish; when cold the composition should just be consistent enough to stand up on the palette. If too thin, heat it again, and add wax; if too thick add turpentine. This vehicle may be used with ordinary oil colors. Before commencing your work heat the wall, and rub in as much vehicle as it will absorb; after the work is finished it should be re-heated, to secure its adhesion to the wall.

Trans.*, vol. xlix., part 2; Muntz on *Encaustic Painting*; Elmes's *Dictionary of the Fine Arts*; W. Cave Thomas, *Methods of Mural Decoration*, London, 1769. (W. C. T.)

ENCAUSTIC TILES. The term "encaustic" as applied to tiles is of modern though somewhat doubtful origin. The art bears no resemblance to the "encaustic painting" mentioned by Pliny and other ancient writers, although the expression (which signifies executed by fire) is perhaps as correctly applied to this manufacture as to the wax-incised pictures of the ancients. The term is, strictly speaking, applied to tiles which are decorated with patterns formed with different colored clays, inlaid in the tile, and fired with it. This art appears to have had its origin in the latter part of the 12th century, but the culminating point of its excellence and popularity was attained during the 13th; and it was extensively used for the decoration of Gothic buildings in connection with each succeeding change in that style of architecture.

In mediæval times the manufacture appears to have been principally carried on in England and Normandy, but examples of ancient tile-pavements of this description are also to be found in Holland and other Continental countries. The greater number of ancient examples are in squares, varying from 4 to 9 inches, but some striking exceptions occur, from which it has been attempted to trace a connection between this art and that of Roman mosaics. Pavements presenting a kind of connecting link between the two have been discovered at Fountains Abbey, and in Prior Crauden's chapel, Ely, in which the tiles are of great variety of form and size; and, instead of the patterns being wholly inlaid in the tiles themselves, the design is, to a large extent, produced by the outlines of the individual pieces, which, in the latter example, are cut to the forms required to be represented, including the subject of the temptation of Adam and Eve, trees, lions, etc., the tesseræ being also enriched with what may be more strictly called encaustic decoration.

Encaustic tiles were almost exclusively used for pavements, but an interesting instance of their employment for wall decoration occurs in the abbey church of Great Malvern, where these tiles have probably been originally used to form a reredos, and bear designs representing Gothic architecture in perspective, having introduced into them the sacred monogram "I.H.S.," the crowned monogram of "Maria," the symbols of the Passion, the Royal Arms, and other devices. This example is also interesting as bearing the date of its manufacture on the margin, "Anno R. R. H. VI. XXXVJ.," that is, the thirty-sixth year of the reign of Henry VI. (1457–8).

Combinations of encaustic tiles forming a cross were frequently used as mortuary slabs; and an example of this kind of monument is in Worcester cathedral *in situ*, whilst the detached component tiles are to be found in other ancient churches.

Many interesting ancient inscriptions are found entering into the designs of encaustic tiles, amongst which is the following, from Great Malvern, which has been deciphered with some difficulty, and rendered into modern English thus—

> "Think, man, thy life
> May not ever endure;
> That thou do'st thy self
> Of that thou art sure;
> But that thou keepest
> Unto thy executor's care,
> If ever it avail thee,
> It is but chance."

A tile from the same place also bears the following quotation from the book of Job, curiously arranged, and beautifully combined with Gothic ornament: "Misereminì mei, miseremini mei saltem, vos amici mei, quia manus Domini tetigit me." The border of this tile bears the names of the evangelists, with the date A.D. MCCCCLVI. The armorial bearings of noble benefactors, and the devices of abbots and other church dignitaries, also enter largely into the decorations of ancient encaustic tiles. Amongst the most interesting examples of these pavements, found *in situ*, is that in the chapter house at Westminster, which about the year 1840 was laid open to view by the removal of a wooden floor previously covering it. It is probably of the time of Henry III., in whose reign it is recorded that the king's little chapel at Westminster was paved with "painted tile,"—"mandatum est, etc., quod parvam capellam apud Westm. tegula picta decenter paveari faciatis." —Rot. Claus. 22 Henry III. M. 19, 1237–38 A.D. The tiles of this pavement comprise subjects which may be taken to represent the king, queen, and the abbot, also the legend of King Edward the Confessor bestowing a ring, as alms, on St. John the Baptist, who appeared to him in the guise of a pilgrim, besides other curious historical designs. The tiles from Chertsey Abbey, Surrey, now in the architectural museum, Westminster, are also amongst the oldest, and, at the same time, the finest and most artistic yet brought to light. They present a remarkable series of illustrations from the English romance of Sir Tristram, and of incidents in the history of Richard Cœur-de-Lion. These tiles were all found in fragments, but have been put together with great care.

Traces of the ancient manufacture of encaustic tiles have been found in several places in England, and the remains of kilns containing tiles in various stages of manufacture have been discovered at Bawsley, near Lynn, in the neighborhood of Droitwich, as well as in other localities, by which an interesting light has been thrown upon the ancient process of production. In almost every instance these tiles were covered with a yellowish glaze, composed principally of lead, similar to that now used in the commoner English earthenware manufactures.

The modern revival of the art dates from the year 1830, when a patent was granted, with this object, to Samuel Wright, a potter of Shelton, in Staffordshire; but he, having failed to bring his experiments to a profitable result at the expiration of the term, a further extension for seven years was granted him. In the year 1844 his patent right was purchased, in equal shares, by the celebrated china manufacturer Herbert Minton and Mr. Fleming St. John, the former carrying on the manufacture at Stoke-upon-Trent, and the latter at Worcester, in partnership with Mr. George Barr, an eminent china manufacturer of that city. Four years later, the firm of which Mr. Minton was the head re-purchased the residue of Mr. St. John's share of the patent right, who about the same time relinquished the manufacture. In the year 1850, Messrs. Maw & Co. purchased the remaining stock of encaustic tiles at the Worcester china works, and, on the expiration of Mr. Wright's patent, commenced the manufacture on those premises, from which they removed to the present site of their works, at Benthall, near Brosely, Shropshire, whence the marls, peculiarly suitable for the purpose, had previously been obtained.

The modern manufacture may be described under two heads—viz., the "plastic" and the "semi-dry" or "dust" processes. The former, which was the only one employed up to the year 1863, is in every essential point the same as that used in mediæval times, differing merely in the greater finish and perfection which modern appliances have effected, and probably also in the material of the moulds. It is not known of what those anciently used were made, but conjecture has suggested wood, fired clay, and stone.

The great difficulty of the manufacture consists in the necessity for introducing into a single tile the variety of different colored clays or "bodies" which together compose the design, it being essential that they should not only be perfected by the same amount of heat in the process of firing, but that they should possess an equal contractile power during each stage of the manufacture.

The tile is first impressed from a plaster of Paris mould, bearing the pattern in relief, and set in a brass frame, upon which fits another frame, the dimensions and depth of which correspond with the size and thickness of the tile; the pattern is thus sunk in the clay to a depth of about one-sixteenth of an inch, in the following manner. The workman first introduces into the mould what may be described as a sheet of refined clay of the desired color for the ground of the pattern; upon this facing, which forms a kind of veneer, is placed a thicker mass of a coarser kind of clay, and the whole is then subjected to screw pressure, which consolidates the two kinds of clays, and at the same time perfectly impresses the pattern of the mould; the superfluous clay is then removed with a scraper, and a second veneering of fine clay, similar to that used for the face, is placed on the back; the tile being removed from the mould, the depressed parts of the design are filled with clay, of one or more colors, by pouring it in in a "slip" or semi-liquid state. The tile is then set aside for twenty-four hours to stiffen, and when the "slip" inlay has become nearly of the same consistency as the tile itself, the face is brought roughly to an even surface, by "spreading" the soft clay with a pallet-knife. The tile is then further allowed to dry till it attains the stiffness of wax, when it is "finished" by scraping the face with a steel scraper, until the inlaid pattern and ground are developed free from superfluous clay, and the edges are cut true to a square, when it is ready for the drying stove. When the drying, which takes from six to ten days, is completed, the tiles are placed in fire-clay boxes, known as "saggers," containing from eight to ten each, which are then stacked, one upon another, in the kiln or oven. The process of firing occupies four days and nights, and has to be conducted with the greatest care, as not only the exact size and hardness of the tiles are dependent upon it, but also the perfection of the colors, with which object it is necessary to raise the heat very gradually, and to secure a regular circulation of air in the oven, so as to produce the exact degree of oxidization needed to bring out the desired colors in the materials used for this purpose. The pyrometers used in this part of the process consist of long narrow tiles, and the degree of heat is judged both by their color and the gradual reduction in length which they undergo, each piece, as it is withdrawn from the oven, being measured in a gauge, with this object,—the total shrinkage of the tile, in the drying and firing, amounting to about 1¼ inches in the foot. For purposes of paving, most of the modern encaustic tiles are used in the "bisque" or unglazed state, the glaze in the ancient tiles having apparently been employed with the object of covering the soft material of the tile itself, and of adding richness to the color. Where glazing is found necessary in the modern tiles it is effected by dipping them in a combination of lead, alkaline salts, felspar, and silica, finely levigated in water, which is fused by passing them through a kiln specially constructed for the purpose.

The semi-dry or "dust" process of manufacturing encaustic tiles is an adaptation of an invention patented in the year 1840 by Richard Prosser, by which articles of various kinds are moulded out of *pulverized clay*, in metal dies, by screw pressure. In the year 1863 Messrs. Boulton and Worthington, engineers of Burslem, patented a process by which the use of powdered clay (hitherto only used for tiles of one color) was applied to the manufacture of encaustic tiles. The design is formed by perforated brass plates,—from one to six or seven being used, according to the nature of the pattern. Where the whole design can be perforated in the plate without detaching such parts as would represent the ground, only one plate is needed; but where there are several concentric rings or similar forms, additional plates are required. Into the perforations of each plate metal rams, attached to a flat plate of iron, are accurately fitted. The metal die in which the tiles are pressed is composed of a thick block and a square frame or "box;" the latter is connected with levers and a balance-weight, so that it can be raised or depressed, either forming a hollow mould, of which the face of the block above mentioned forms the bottom, or depressed in such a way as to leave the face of the block standing above it, in which latter position it is ready for the commencement of the process. The perforated plates first mentioned are then, in succession, placed upon the face of the block, being kept in position by two pins fixed to the frame of the die, corresponding with holes made in their margin. The perforations of the brass plate being filled with powdered clay of the desired color, this is so far compressed, by means of the metal ram, as to allow both the ram and the plate to be removed together, leaving the compressed dust (representing the pattern of the tile in relief) on the block or face plate. In cases where a number of plates are necessary, the pattern is thus *built up*, each adding such a part as can be perforated in a single plate. The frame is then raised, so as to form a mould of the required depth, which being filled with powdered clay, intended to form both the ground of the pattern and the substance of the tile, the whole mould or die is slid, in a groove provided for the purpose, under the screw press, to which is attached a plate covering the mould, and resting on the top of the movable frame; this, on pressure being applied, forces down the frame until the powdered clay is thoroughly consolidated and incorporated with that part forming the design. On the pressure being relieved, the die is drawn from beneath the press, the frame is forced down by means of the levers to which it is attached, and the tile is left resting, face downwards, on the block, when it is ready for the drying-stove, the subsequent treatment being the same as in the plastic process. This process affords the advantage of much greater rapidity in execution than can be effected by the plastic method, and as the tile undergoes little or no shrinkage in the desiccation of the small amount of moisture which is needed to make the particles of the dust combine under pressure, the risk of distortion in the process of drying is reduced to a minimum, but the heavy prime cost of the perforated brass plates necessarily confines this otherwise valuable invention to such designs as are most largely in demand.

The modern application of encaustic tiles is by no means confined to the ecclesiastical purposes for which they were mainly used in mediæval times, although for this purpose many of the ancient designs have been reproduced, and the rough execution of the old examples has been imitated with striking fidelity. Some of the most eminent architects of recent years have exercised their skill in the production of designs more suitable for domestic purposes; and pavements of these tiles, combined with other kindred manufactures (for which see Mosaics and Tiles), have become an almost universal part of the permanent decoration of the better class of public and private buildings, for which purpose they are also largely exported to the colonies and foreign countries, superseding the perishable forms of flooring, and at the same time rendering unnecessary any decorative coverings. (A. M.)

ENCHASING, or **Chasing**, is the art of producing figures and ornamental patterns, either raised or indented, on metallic surfaces by means of steel tools or punches. It is practised extensively for the ornamentation of gold and silversmith work, electro-plate, and similar objects, being employed to produce bold flutings and bosses, and in another manner utilized for imitating engraved surfaces. The chaser first outlines the pattern on the surface he is to ornament, after which, if the work involves bold or high embossments, these are blocked out by a process termed "snarling." The snarling iron is a long iron tool turned up at the end, and made so that when securely fastened in a vice the upturned end can reach and press against any portion of the interior of the vase or other object to be chased. The part to be raised being held firmly against the upturned point of the snarling iron, the workman gives the shoulder or opposite end of the iron a sharp blow, which causes the point applied to the work to give it a percussive stroke, and thus throw up the surface of the metal held against the tool. When the blocking out from the interior is finished, or when no such embossing is required, the object to be chased is filled with molten pitch, which is allowed to harden. It is then fastened to a sand-bag, and with hammer and a multitude of small punches of different outline the whole details of the pattern, lined, smooth, or "matt," are worked out. Embossing and stamping from steel dies and rolled ornaments are now taking the place of chased ornamentations in the cheaper kinds of plated work.

ENCINA or **Enzina, Juan del**, the founder of the Spanish drama, was born in 1468 or 1469, either in the city of Salamanca or more probably in the neighboring village of Encinas. After studying at the university of Salamanca under the patronage of the chancellor Don Gutierre de Toledo, brother of Don Garcia, count of Alva, he proceeded to Madrid, and became, when about twenty-five years of age, a member of the household of Don Fadrique de Toledo and Dona Isabel Pimental, the first duke and duchess of Alva. In or about the year 1492—the year, that is, in which Columbus added the New World to the dominions of Spain—the poet began to entertain his patrons by the representation of comedies of his own composition, in which he sometimes played the part of the *Gracioso*, or buffoon. In 1496, under the title of *Cancionero*, he published a collection of nine dramatic and numerous lyrical poems, divided into four parts, dedicated respectively to their Catholic majesties, to the prince Don Juan, to the dukes of Alva, and to Don Garcia de Toledo. Some years afterwards he went to Rome, joined the clerical order, attracted the attention of Leo X. by his skill in music, and was appointed his *maestro di capella*. Great praise was bestowed by his contemporaries on a farce, *Placida e Victoriano*, published by him in 1514; but of the justness of their criticism we have no means of judging, since, owing in all probability to its insertion in the *Index Expurgatorius*, all copies of it have perished. In 1519 the poet went to Jerusalem in company with the marquis of Tarifa, Don Fadrique Enriquez Afan de Riberon; but he was again in Rome about the middle of 1520, and in the following year published his *Trabagia o Via Sacra de Hierusalem*, a versified account of his journey, which has since been several times reprinted along with the marquis's narrative (Rome, 1721; Madrid, 1786). Shortly afterwards he was appointed prior of Leon, and returned to Spain. His death took place at Salamanca in 1534, and he was buried in the cathedral of that city. His *Cancionero*, which was reprinted five times in the course of the 16th century (Seville, 1501; Burgos, 1503; Salamanca, 1509, in company with the coplas of Zambardo; Saragossa, 1512 and 1516), is preceded by a prose treatise, among the first of its kind, on the condition of the poetic art in Spain. The dramatic poems, of interest mainly as marking the transition from the purely ecclesiastical to the secular stage, comprise "mysteries," as *The Passion of our Precious Redeemer*, *The most Sacred Resurrection of Christ*, and pastoral plays (*Eglogas*), as *The Knight turned Shepherd*, *The Shepherds become Courtiers*, *The Triumph of Love*. Seven of the number are reprinted in Bohl de Faber, *Teatro español*, Hamburg, 1832. After the author's death there appeared in 1556 without rubric, *Documento e instruccion para las doncellas desposadas y recien casadas con una justa d'amores.* See Barrera, *Catalogo del Teatro antiguo español.*

ENCKE, Johann Franz (1791–1865), a celebrated astronomer, was born at Hamburg on the 23d September, 1791. He received his early education from his father, who was a clergyman, and he afterwards studied at the university of Göttingen, devoting himself specially to astronomy under the instruction of Professor Gauss. In 1813–14 he served in the Hanseatic legion in the war with Napoleon, and in 1815 he became a lieutenant of artillery in the Prussian service. When peace was concluded he resumed his astronomical studies at Göttingen until 1817, when he was appointed by Lindenau the Saxon minister of state to a post in the Observatory of Seeberg, near Gotha. In 1822–3 he published at Gotha two volumes, entitled *Die Entfernung der Sonne*, in which the various observations of the transits of Venus in 1761 and 1769 were carefully reconsidered, and the calculations verified and corrected. One of the earliest subjects to which his attention was directed was the determination of the orbit of the comet observed by Pons at Marseilles in November, 1818. He calculated the period of its recurrence at about three and a quarter years, and conjectured it to be the same comet that had appeared in 1786, 1795, and 1805. Upon the data he possessed he was able to predict its reappearance in 1822, and he stated also that it would probably be invisible in Europe. His prediction was almost exactly verified, the comet being observed in New South Wales on the 3d June, 1822, and the time of its perihelion passage being within three hours of that which he had computed. From the elements supplied by this observation he was able to foretell more accurately its recurrences in 1825 and 1828, and after the latter of these he determined its exact orbit. After the observation of 1832 he determined the period of its revolution as 3·29 years, with a gradual acceleration which he ascribed to the existence of a resisting medium. The comet is known as Encke's comet. In 1825 Encke was appointed to succeed Bode as director of the Royal Observatory at Berlin, a situation which he filled with great ability until within a year of his death. In 1830 he became editor of the Berlin *Astronomisches Jahrbuch*, to which he contributed a large number of valuable papers. The observations taken under his direction at the Berlin Observatory were recorded and published in a series of volumes, of which the first appeared in 1840. Of his many other contributions to astronomical literature may be mentioned his new method for computing perturbations, his dissertation *De Formulis Dioptricis* (1845), and his work on the relation of astronomy to the other sciences, which was published in 1846. Encke was one of the foreign members of the Royal Society of London, and in 1840 he was created a knight by the king of Prussia. He died at Spandau on September 2, 1865.

ENCYCLOPÆDIA. The Greeks seem to have understood by encyclopædia (*ἐγκυκλοπαιδεία*, or *ἐγκύκλιος παιδεία*) instruction in the whole circle or complete system of learning—education in arts and sciences. Thus Pliny, in the preface to his *Natural History*, says that his book treated of all the subjects of the encyclopædia of the Greeks, "Jam omnia attingenda quæ Græci *τῆς ἐγκυκλοπαιδείας* vocant." Quintilian (*Inst. Orat.*, i. 10) directs that before boys are placed under the rhetorician they should be instructed in the other arts, "ut efficiatur orbis ille doctrinæ quam Græci *ἐγκυκλοπαιδείαν* vocant." Galen (*De victus ratione in morbis acutis*, c. 11) speaks of those who are not educated *ἐν τῇ ἐγκυκλοπαιδείᾳ* In these passages of Pliny and Quintilian, however, from one or both of which the modern use of the word seems to have been taken, *ἐγκύκλιος παιδεία* is now read, and this seems to have been the usual expression. Vitruvius (lib. vi. præf.) calls the encyclios or *ἐγκύκλιος παιδεία* of the Greeks "doctrinarum omnium disciplina," instruction in all branches of learning. Strabo (lib. iv. cap. 10) speaks of philosophy *καὶ τὴν ἄλλην παιδείαν ἐγκύκλιον*. Tzetzes (*Chiliades*, xi. 527), quoting from Porphyry's *Lives of the Philosophers*, says that *ἐγκύκλια μαθήματα* was the circle of grammar, rhetoric, philosophy, and the four arts under it, arithmetic, music, geometry, and astronomy. Zonaris explains it as grammar, poetry, rhetoric, philosophy, mathematics, and simply every art and science (*ἁπλῶς πᾶσα τέχνη καὶ ἐπιστήμη*), because sophists go through them as through a circle. The idea seems to be a complete course of instruction in all parts of knowledge. An epic poem was called cyclic when it contained the whole mythology; and among physicians *κύκλῳ θεραπεύειν*, cyclo curare (Vegetius, *De Arte Veterinaria*, ii. 5, 6), meant a cure effected by a regular and prescribed course of diet and medicine (see Wower, *De Polymathia*, c. 24, § 14). The word encyclopædia was probably first used in English by Sir Thomas Elyot. "In an oratour is required to be a heape of all maner of lernyng: whiche of some is called the worlde of science, of other the circle of doctrine, whiche is in one worde of greke Encyclopedia."—*The Governour*, bk. i. chap. xiii. In his Latin dictionary, 1538, he explains "Encyclios et Encyclia, the cykle or course of all doctrines," and "Encyclopedia, that lernynge whiche comprehendeth all lyberall science and studies." The term does not seem to have been used as the title of a book by the ancients or in the Middle Ages. The edition of the works of Joachimus Fortius Ringelbergius, printed at Basel in 1541, is called on the title-page *Lucubrationes vel potius absolutissima κυκλοπαιδεια*. Paulus Scalichius de Lika, an Hungarian count, wrote *Encyclopædiæ seu Orbis Disciplinarum Epistemon*, Basileæ, 1599, 4to. Alsted published in 1608 *Encyclopædia Cursus Philosophici*, which he afterwards expanded into his great work, first published in 1620, called without any limitation *Encyclopædia*, because it treats of everything that can be learned by man in this life. This is now the most usual sense in which the word encyclopædia is used—a book treating of all the various kinds of knowledge—and it has become in modern times the common title of such books. Cyclopædia was formerly sometimes used, but is now retained only in English, and is not merely without any appearance of classical authority, but is etymologically less definite, complete, and correct. For as Cyropædia means "the instruction of Cyrus," so cyclopædia may mean "instruction of a circle." Vossius says, "Cyclopædia is sometimes found, but the best writers say encyclopædia" (*De Vitiis Sermonis*, 1645, p. 402). Gesner says, "*κύκλος* est *circulus*, quæ figura est simplicissima et perfectissima simul: nam incipi potest ubicunque in illa et ubicunque cohæret. *Cyclopædia* itaque significat omnem doctrinarum scientiam inter se cohærere. *Encyclopædia* est institutio in illo circulo." (*Isagoge*, 1774, i. 40.) In a more restricted sense, encyclopædia means a system or classification of the various branches of knowledge, a subject on which many books have been published, especially in Germany, as Schmid's *Allegemeine Encyklopädie und Methodologie der Wissenschaften*, Jena, 1810, 4to, 241 pages. In this sense the *Novum Organum* of Bacon has often been called an encyclopedia. But it is "a grammar only of the sciences: a cyclopædia is not a grammar, but a dictionary; and to confuse the meanings of grammar, and dictionary is to lose the benefit of a distinction which it is fortunate that terms have been coined to convey" (*Quarterly Review*, cxiii. 354). Fortunius Licetus, an Italian physician, entitled several of his dissertations on Roman altars and other antiquities encyclopædias (as, for instance, *Encyclopædia ad Aram mysticam Nonarii*, Patavia, 1631, 4to), because in composing them he borrowed the aid of all the sciences. The *Encyclopædia Moralis* of Marcellinus de Pise, Paris, 1646, fol. 4 vols., is a series of sermons. Encyclopædia is often used to mean a book which is, or professes to be, a complete or very full collection or treatise relating to some particular subject, as Blaine's excellent work, *The Encyclopædia of Rural Sports*, London, 1852, 8vo; *The Encyclopædia of Wit*, London, 1803, 12mo; *The Vocal Encyclopædia*, London, 1807, 16mo, a collection of songs, catches, etc. The word is more frequently used for an alphabetical dictionary treating fully of some science or subject, as Murray, *Encyclopædia of Geography*, London, 1834, 8vo; Lefebvre Laboulaye, *Encyclopédie Technologique: Dictionnaire des Arts et Manufactures*, Paris, 1845–47, 8vo, 2 vols.; Holtzendorff, *Encyclopädie der Rechtswissenschaft*, Leipzig, 1870, etc., 8vo.

The most ancient encyclopædia extant is Pliny's *Natural History* in 37 books (including the preface) and 2493 chapters, which may be thus described generally:—book 1, preface; book 2, cosmography, astronomy, and meteorology; books 3 to 6, geography; books 7 to 11, zoology, including man, and the invention of the arts; books 12 to 19, botany; books 20 to 32, medicines, vegetable and animal remedies, medical authors, and magic; books 33 to 37, metals, fine arts, mineralogy, and mineral remedies. Pliny, who died 79 A.D., was not a naturalist, a physician, or an artist, and collected his work in his leisure intervals while engaged in public affairs. He says it contains 20,000 facts (too small a number by half, says Lemaire), collected from 2000 books by 100 authors. Hardouin has given a list of 464 authors quoted by him. His work was a very high authority in the Middle Ages, and 43 editions of it were printed before 1536.

Martianus Minæus Felix Capella, an African, wrote about 470, in mingled verse and prose, a sort of encyclopædia, which is important from having been regarded in the Middle Ages as a model storehouse of learning, and used in the schools where the scholars had to learn the verses by heart, as a text-book of high class education in the arts. It is sometimes entitled *Satyra*, or *Satyricon*, but is usually known as *De Nuptiis Philologiæ et Mercurii*, though this title is sometimes confined to the first two books, a rather confused allegory ending with the apotheosis of Philologia and the celebration of her marriage in the milky way, where Apollo presents to her the seven liberal arts, who, in the succeeding seven books, describe their respective branches of knowledge, namely, grammar, dialectics (divided into metaphysics and logic), rhetoric, geometry (geography, with some single geometrical propositions), arithmetic (chiefly the properties of numbers), astronomy, and music (including poetry. The style is that of an African of the 5th century, full of grandiloquence, metaphors, and strange words. He seldom mentions his authorities, and sometimes quotes authors whom he does not at all seem to have read. His work was frequently copied in the Middle Ages by ignorant transcribers, and was eight times printed from 1499 to 1599. The best annotated edition is by Kopp, Frankfort, 1836, 4to, and the most convenient and the best text is that of Eyssenstadt, Lipsiæ, 1866, 8vo.

Isidore, bishop of Seville from 600 to 630, wrote *Etymologiarum libri XX.* (often also entitled his *Origines*) at the request of his friend Braulio, bishop of Saragossa, who after Isidore's death divided the work into books, as it was left unfinished, and divided only into titles.

The tenth book is an alphabet of 625 Latin words, not belonging to his other subjects, with their explanations as known to him, and often with their etymologies, frequently very absurd. The other books contain 448 chapters, and are:—1, grammar (Latin); 2, rhetoric and dialectics; 3, the four mathematical disciplines—arithmetic, geometry, music, and astronomy; 4, medicine; 5, laws and times (chronology), with a short chronicle ending in 627; 6, ecclesiastical books and offices; 7, God, angels, and the orders of the faithful; 8, the church and sects; 9, languages, society, and relationships; 11, man and portents; 12, animals, in eight classes, namely, pecora et jumenta, beasts, small animals (including spiders, crickets, and ants), serpents, worms, fishes, birds, and small winged creatures, chiefly insects; 13, the world and its parts; 14, the earth and its parts, containing chapters on Asia, Europe, and Libya—that is, Africa; 15, buildings, fields, and their measures; 16, stones (of which one is echo) and metals; 17, de rebus rusticis; 18, war and games; 19, ships, buildings, and garments; 20, provisions, domestic and rustic instruments.

Isidore appears to have known Hebrew and Greek, and to have been familiar with the Latin classical poets, but he is a mere collector, and his derivations given all through the work are not unfrequently absurd, and, unless when very obvious, will not bear criticism. He seldom mentions his authorities except when he quotes the poets or historians. Yet his work was a great one for the time, and for many centuries was a much valued authority and a rich source of material for other works, and he had a high reputation for learning both in his own time and in subsequent ages. His *Etymologies* were often imitated, quoted, and copied. MSS. are very numerous: Antonio (whose editor, Bayer, saw nearly 40) says, "plures passimque reperiuntur in bibliothecarum angulis." This work was printed nine times before 1529.

Hrabanus Maurus, whose family name was Magnentius, was educated in the abbey of Fulda, ordained deacon in 802 ("Annales Francorum" in Bouquet, *Historiens de la France*, v. 66), sent to the school of St. Martin of Tours then directed by Alcuin, where he seems to have learned Greek, and is said by Trithemius to have been taught Hebrew, Syriac, and Chaldee by Theophilus an Ephesian. In his *Commentaries on Joshua* (lib. ii. c. 5), he speaks of having resided at Sidon. He returned to Fulda and taught the school there. He became abbot of Fulda in 822, resigned in April, 842, was ordained archbishop of Mayence 26th July, 847, and died 4th February, 856. He compiled an encyclopædia *De universo* (also called in some MSS. *De universali natura*, *De natura rerum*, and *De origine rerum*) in 22 books and 325 chapters. It is chiefly a rearrangement of Isidore's *Etymologies*, omitting the first four books, half of the fifth, and the tenth (the seven liberal arts, law, medicine, and the alphabet of words), and copying the rest, beginning with the seventh book, verbally, though with great omissions, and adding (according to Ritter, *Geschichte der Philosophie*, vii. 193, from Alcuin, Augustine, or some other accessible source) the meanings given in the Bible to the subject-matter of the chapter; while things not mentioned in Scripture, especially such as belong to classical antiquity, are omitted, so that his work seems to be formed of two alternating parts. His arrangement of beginning with God and the angels long prevailed in methodical encyclopædias. His last six books follow very closely the order of the last five of Isidore, from which they are taken. His omissions are characteristic of the diminished literary activity and more contracted knowledge of his time. His work was presented to Louis the German, king of Bavaria, at Hersfeld in October, 847, and was printed in 1473, fol., probably at Venice, and again at Strasburg by Mentelin about 1472–75, fol., 334 pages.

Michael Constantine Psellus, the younger, wrote *Διδασκαλία παντοδαπή*, dedicated to the emperor Michael Ducas, who reigned 1071–78. It was printed by Fabricius in his *Bibliotheca Græca*, 1712, vol. v., in 186 pages 4to and 193 chapters, each containing a question and answer. Beginning with divinity, it goes on through natural history and astronomy, and ends with chapters on excessive hunger, and why flesh hung from a fig tree becomes tender. As collation with a Turin MS. showed that 35 chapters were wanting, Harles has omitted the text in his edition of Fabricius, and gives only the titles of the chapters (x. 84–88).

The author of the greatest encyclopædia of the Middle Ages, Vincentius Bellovacensis, or Belvacensis, most probably a native of Beauvais or of the Beauvaisis, was a Dominican friar, called by Louis IX. of France, on his founding Royaumont, a Cistercian monastery, in 1228, to fill the office of lector. He seems also to have been royal librarian, and Louis IX. paid for copying and buying many books for him. Fifteen different dates from 1240 to 1334 have been proposed for his death, but the most probable and the best supported by evidence seems to be 1264. His great work, called *Bibliotheca mundi*, or *Speculum majus*, *quadruplex*, or *triplex*, is only the third part of what he had prepared and abridged "ad fratrum preces et consilium prelati." The edition of 1624 contains 4327 folio pages of very small type. That the work excited great attention, and was much used at all times, is proved by the great number of MSS. in all libraries, of which nearly 80 have been described, though no general notice of them has been published. In his prologue or general preface, which is prefixed to each of the three genuine parts, he says it is called *Speculum* because it briefly contains almost everything he could collect from innumerable books which is worthy of speculation, that is, of admiration or imitation, done or said in the visible and invisible world from the beginning to the end, and even future things. He was so anxious that the names of the authors quoted should not be lost or transposed in copying that he wrote them, not on the margin, but in the text itself, "inter lineas ipsas sicut in decretis;" therefore Thomasius (*De Plagio*, 542–75) acquits him of plagiarism, because he represents his work as a collection and acknowledges all quotations.

The *Speculum Majus* describes—first, natural things; secondly, human doctrines, grammatical, literary, moral and political, including jurisprudence, mathematics, and physics; thirdly, ancient history, sacred and profane, with modern history, civil, literary, and, above all, ecclesiastical. To these three genuine parts a fourth was added, called *Speculum morale*. The first part, *Speculum naturale*, finished in 1250, called in some MSS. *Speculum in Hexameron*, because arranged according to the order of the creation, contains 32 books and 3718 chapters. Book 1 treats of the Creator and the angels; 2, the sensible world and the work of the first day, including light, colors, and demons; 3, the second day, the firmament; 5 to 14, the third day,—book 5 waters, 6 the earth, 7 minerals and metals, 9–14 botany, containing eight alphabetical lists, aromatic plants (Absinthium to Erigeron) 198 names, cultivated plants (Abrotanum to Zinziber) 112 names, the others much shorter; book 15, fourth day, astronomy and technical chronology; book 16, fifth day, birds; book 17, fishes (list of 98 names, including sepia, spongia) and marine monsters (45 names); books 18 to 22, sixth day, animals; 23 to 28, man; 29, de universo, relating to the operations of the Creator since the creation, miracles, original sin, etc. The last three books form a sort of appendix:—book 30, nature of things; 31, natural history of human life; 32, places and times. The second part, *Speculum doctrinale*, contains 17 books and 2374 chapters; book 1, the fall, studies, doctors, words, with an alphabetical dictionary of about 2300 words—Abavus to Zodia; book 2, a very full grammar, with 45 chapters on verbs; book 3, logic, rhetoric, and poetry (with 29 fables); 4, 5, monastic science; 6, economic science; 7, politics: 8, legal actions; 9, 10, crimes; 11, mechanical arts: 12, practical medicine; 13, 14, theoretic medicine; 15, physics; 16, mathematics, including metaphysics; 17, theology. Vincent had an accurate knowledge of Arabic figures and of the decimal notation, and his book was probably the first written in France in which they were explained. He does not mention mechanics or optics by name. The third part, *Speculum morale*, is undoubtedly not by Vincent de Beauvais. It was written, according to Quetif, between 1310 and 1325, and is not mentioned in the prologue in any MS. written before 1310, in which the division of the work is said to be threefold, and the *Speculum historiale* is called the third part, and not the fourth, as it is in the later MSS. No MS. of the *Speculum morale* contains the prologue. It is divided into 3 books and 347 distinctions, subdivided into articles. Scholastic arguments are more frequent, authors rarely named, and contradictory doctrines placed together. It is chiefly taken from Peter de Tarentasia on the *Sentences of Peter Lombard*, Stephen de Borbone on the *Seven Gifts of the Spirit*, Richard de Middleton, the anonymous *De consideratione novissimorum*, and, above all, from the *Summa Theologiæ* of Thomas Aquinas. The fourth part, *Speculum historiale*, in 31 books and 3793 chapters, contains a history of the world from the creation to 1254, with 24 chapters on the death of men, the end of the world, which he places with St. Hildegard in 2376 A.D., the reign of Antichrist, the last judgment, and the renewal of the universe. In more ancient times his chief guides are Peter Comestor (died 1178) and the Cistercian Helinand (died 1223). He mentions Turpin as the principal historian of Charlemagne. No one, says Quetif, has written the history of his time with more accuracy and truth, and greater freedom from all flattery. Jacob Van Maerlant translated this *Speculum* into Flemish verse, and continued it to 1273. A French translation was made by Jean de Vignay (a canon hospitaller of St. Jacques du Hautpas, who died in 1341), at the request of Joanna of Burgundy, queen of Philip VI. of France, and printed by Verard, Paris, 1495–96, fol. 5 vols.

Vincent de Beauvais has preserved several works of the Middle Ages, and gives extracts from many lost classics and valuable readings of others, and has done more than any other mediæval writer to awaken a taste for classical literature. Fabricius (*Bibl. Græca*, 1728, xiv. pp. 107–25) has given a list of 328 authors, Hebrew, Arabic, Greek, and Latin, quoted in the *Speculum naturale*. To these should be added about 100 more for the *doctrinale* and *historiale*. As he did not know Greek or Arabic, he used Latin translations. The best edition of the *Speculum maqus* is the first, printed at Strasburg, by Mentelin, 1469 ? to 1473, fol. 10 vols. The three Venice editions of 1484, 1493–4, and 1591, fol. 4 vols., are very imperfect and incorrect. The last edition. Duaci, 1624, fol. 4 vols, by the Benedictines of St Vaast of Arras, is equally incorrect, and Vincent's readings of ancient texts are replaced by the current readings of the time.

Brunetto Latini of Florence (born 1230, died 1294), the master of Dante and Guido Cavalcanti, while an exile in France between 1260 and 1267, wrote in French *Li Livres dou Tresor*, in 3 books and 413 chapters. Book i. contains the origin of the world, the history of the Bible and of the foundation of governments, astronomy, geography, and lastly natural history, taken from Aristotle, Pliny, and the old French Bestiaries. The first part of Book ii., on morality, is from the *Ethics* of Aristotle, which Brunetto had translated into Italian. The second part is little more than a copy of the well-known collection of extracts from ancient and modern moralists, called the *Moralities of the Philosophers*, of which there are many MSS. in prose and verse. Book iii., on politics, begins with a treatise on rhetoric, chiefly from Cicero *De Inventione*, with many extracts from other writers and Brunetto's remarks. The last part, the most original and interesting of all, treats of the government of the Italian republics of the time. Like many of his contemporaries, Brunetto revised his work, so that there are two editions, the second made after his return from exile. MSS. are singularly numerous, and exist in all the dialects then used in France. Others were written in Italy. It was translated into Italian in the latter part of the 13th century by Bono Giamboni, and was printed at Trevigi, 1474, fol., Venice, 1528 and 1533. The *Tesoro* of Brunetto must not be confounded with his *Tesoretto*, an Italian poem of 2937 short lines. Napoleon I. had intended to have the French text of the *Tesoro* printed with commentaries, and appointed a commission for the purpose. It was at last published in the *Collection des Documents inédits*, Paris, 1863, 4to, 772 pages, edited by Chabaille from 42 MSS.

Bartholomeus de Glanvilla, an English Franciscan friar, wrote about 1360 a most popular work, *De proprietatibus rerum*, in 19 books and 1230 chapters.

Book 1 relates to God; 2, angels; 3, the soul; 4, the substance of the body; 5, anatomy; 6, ages; 7, diseases; 8, the heavens (astronomy and astrology); 9, time; 10, matter and form; 11, air; 12, birds (including insects, 38 names, Aquila to Vespertilio); 13, water (with fishes); 14, the earth (42 mountains, Ararath to Ziph); 15, provinces (171 countries, Asia to Zeugia); 16, precious stones (including coral, pearl, salt, 104 names, Arena to Zinguttes); 17, trees and herbs (197, Arbor to Zucarum); 18, animals (114, Aries to Vipera); 19, colors, scents, flavors, and liquors, with a list of 36 eggs (Aspis to Vultur). Some editions add book 20, accidents of things—that is, numbers, measures, weights, and sounds. The Paris edition of 1574 has a book on bees.

There were 15 editions before 1500. An English translation was completed 11th February, 1398, by John Trevisa, and printed by Wynkyn de Worde, Westminster, 1495? fol.; London, 1533, fol.; and with considerable additions by Stephen Batman, a physician, London, 1582, fol. It was translated into French by Jehan Corbichon at the command of Charles V. of France, and printed 14 times from 1482 to 1556. A Dutch translation was printed in 1479, and again at Harlem, 1485, fol.; and a Spanish translation by Padre Vincinte de Burgos, Tholosa, 1494, fol.

Petrus Berchorius, a French Benedictine, prior of the abbey of St. Eloy in Paris, where he died in 1362, wrote a kind of encyclopædia, chiefly relating to divinity, in three parts:—*Reductorium morale super totam Bibliam*, 428 *mortaliates* in 34 books on the Bible from Genesis to Apocalypse; *Reductorium morale de proprietatibus rerum*, in 14 books and 958 chapters, a methodical encyclopædia or system of nature on the plan of Bartholomew de Glanville, and chiefly taken from him (Berchorius places animals next after fishes in books 9 and 10, and adopts as natural classes *volatilia*, *natatilia*, and *gressibilia*); *Dictionarius*, an alphabetical dictionary of 3514 words used in the Bible, with moral expositions, occupying in the last edition 1558 folio pages. The first part was printed 11 times from 1474 to 1515, and the third 4 times. The three parts were printed together as *Petri Berchorii opera omnia* (an incorrect title, for he wrote much besides), Moguntiæ, 1609, fol. 3 vols., 2719 pages; Coloniæ Agrippinæ, 1631, fol. 3 vols.; *ib.* 1730–31, fol. 6 vols. 2570 pages.

A very popular small encyclopædia, *Margarita philosophica*, in 12 books, divided into 26 tractates and 573 chapters, was written by George Reisch, a German, prior of the Carthusians of Freiburg, and confessor of the emperor Maximilian I. Books 1–7 treat of the seven liberal arts; 8, 9, principles and origin of natural things; 10, 11, the soul, vegetative, sensitive, and intellectual; 12, moral philosophy. The first edition, Heidelberg, 1496, 4to, was followed by 8 others to 1535. An Italian translation by the astronomer Giovanno Paolo Gallucci was published at Venice in 1594, 1138 small quarto pages, of which 343 consist of additional tracts appended by the translator.

Raphael Maffei, called Volaterranus, being a native of Volterra, where he was born in 1451 and died 5th January, 1522, wrote *Commentarii Urbani*, Rome, 1506, fol., in 38 books, so called because written at Rome. This encyclopædia, printed eight times up to 1603, is remarkable for the great importance given to geography, and also to biography, a subject not included in previous encyclopædias. Indeed, the book is formed of three nearly equal parts,—geographia, 11 books; anthropologia (biography), 11 books; and philologia, 15 books. The books are not divided into short chapters in the ancient manner, like those of its predecessors. The edition of 1603 contains 814 folio pages. The first book consists of the table of contents and a classed index; books 2–12, geography; 13–23, lives of illustrious men, the popes occupying book 22, and the emperors book 23; 24–27, animals and plants; 28, metals, gems, stones, houses, and other inanimate things; 34, de scientiis cyclicis (grammar and rhetoric); 35, de scientiis mathematicis (arithmetic, geometry, optica, catoptrica, astronomy, and astrology); 36–38, Aristotelica (on the works of Aristotle).

George Valla, born about 1430 at Placentia, and therefore called Placentinus, died at Venice in 1499 while lecturing on the immortality of the soul. Aldus published his work, edited by his son John Peter Valla, *De expetendis et fugiendis rebus*, Venetiis, 1501, fol. 2 vols.

It contains 49 books and 2119 chapters. Book 1 is introductory, on knowledge, philosophy, and mathematics, considered generally (he divides everything to be sought or avoided into three kinds—those which are in the mind, in the body by nature or habit, and thirdly, external, coming from without); books 2–4, arithmetic; 5–9, music; 10–15, geometry (including Euclid and mechanics,—book 15 being in three long chapters—de spiritualibus, that is, pneumatics and hydraulics, de catoptricis, and de optice); 16–19, astrology (with the structure and use of the astrolabe); 20–23, physics (including metaphysics); 24–30, medicine; 31–34, grammar; 35–37, dialectics; 38, poetry; 39, 40, rhetoric; 41, moral philosophy; 42-44, economics; 45, politics; 46–48, de corporis commodis et incommodis, on the good and evil of the body (and soul); 49, de rebus externis, as glory, grandeur, etc.

Antonio Zara, born 1574, made bishop of Petina in Istria 1600, finished 17th January, 1614, a work published as *Anatomia Ingeniorum et Scientarium*, Venetiis, 1615, 4to, 664 pages, in four sections and 54 membra. The first section, on the dignity and excellence of man, in 16 membra, considers him in all his bodily and mental aspects. The first membrum describes his structure and his soul, and in the latter part contains the author's preface, the deeds of his ancestors, an account of himself, and the dedication of his book to Ferdinand archduke to Austria. Four membra treat of the discovery of character by chiromancy, physiognomy, dreams, and astrology. The second section treats of 16 sciences of the imagination,—writing, magic, poetry, oratory, courtiership (aulicitas), theoretical and mystic arithmetic, geometry, architecture, optics, cosmography, astrology, practical medicine, war, government. The third section treats of 8 sciences of intellect,—logic, physics, metaphysics, theoretical medicine, ethics, practical jurisprudence, judicature, theoretical theology. The fourth section treats of 12 sciences of memory,—grammar, practical arithmetic, human history, sacred canons, practical theology, sacred history, and lastly the creation and the final catastrophe. The book, now very rare, is well arranged, with a copious index, and is full of curious learning.

Johann Heinrich Alsted, born 1588, died 1638, published *Encyclopædia septem tomis distincta*, Herbornæ Nassoviorum 1630, fol. 7 vols., 2543 pages of very small type. It is in 35 books, divided into 7 classes, preceded by 48 synoptical tables of the whole, and followed by an index of 119 pages.

I. Præcognita disciplinarum, 4 books, hexologia, technologia, archelogia, didactica—that is, on intellectual habits and on the classification, origin, and study of the arts. II. Philology, 6 books, lexica, grammar, rhetoric, logic, oratory, and poetry: book 5, lexica, contains dictionaries explained in Latin of 1076 Hebrew, 842 Syriac, 1934 Arabic, 1923 Greek, and 2092 Latin words, and also nomenclator technologiæ, etc., a classified vocabulary of terms used in the arts and sciences, in Latin, Greek, and Hebrew, filling 34 pages; book 6 contains Hebrew, Aramaic, Greek, Latin, and German grammars; book 10, poetica, contains a list of 61 Rotwelsch words. III. Theoretic philosophy, 10 books:—book 11, metaphysics; 12, pneumatica (on spirits); 13, physics; 14, arithmetic; 15, geometry; 16, cosmography; 17, uranometria (astronomy and astrology); 18, geography (with maps of the Old World, eastern Mediterranean, and Palestine under the Old and New Testaments, and a plate of Noah's ark); 19, optics; 20, music. IV. Practical philosophy, 4 books:—21, ethics; 22, economics (on relationships);

23, politics, with florilegium politicum, 119 pages of extracts from historians, philosophers, and orators; 24, scholastics (on education, with a florilegium of 25 pages). V. The three superior faculties:—25, theology; 26, jurisprudence; 27, medicine (ending with the rules of the Salernian school). VI. Mechanical arts in general:—book 28, mathematical mechanical arts; book 29, agriculture. gardening, care of animals, baking, brewing, preparing medicines, metallurgy (with mining); book 30, physical mechanical arts—printing, dialling, etc. Under pædutica (games) is Vida's Latin poem on chess, and one by Leuschner on the Ludus Lorzius. VII. Farragines disciplinarum, 5 books:—31, mnemonics; 32, history; 33, chronology; 34, architecture; 35, quodlibetica, miscellaneous arts, as magic, cabbala, alchemy, magnetism, etc., with others apparently distinguished and named by himself, as, paradoxologia, the art of explaining paradoxes; dipnosophistica, the art of philosophizing while feasting; cyclognomica, the art of conversing well de quovis scibili; tabacologia, the nature, use, and abuse of tobacco, etc.,—in all, 35 articles in this book.

Alsted's encyclopædia was received with very great applause, and was highly valued. Lami (*Entretiens*, 1684, p. 188) thought it almost the only encyclopædia which did not deserve to be despised. Alsted's learning was very various, and his reading was very extensive and diversified. He gives few references, and Thomasius charges him with plagiarism, as he often copies literally without any acknowledgment. He wrote not long before the appearance of encyclopædias in modern languages superseded his own and other Latin books, and but a short time before the alphabetical arrangement began to prevail over the methodical. His book was reprinted, Lugduni, 1649, fol. 4 vols., 2608 pages.

Jean de Magnon, historiographer to the king of France, undertook to write an encyclopædia in French heroic verse, which was to fill ten volumes of 20,000 lines each, and to render libraries merely a useless ornament. But he did not live to finish it, as he was killed at night by robbers on the Pont Neuf in Paris, in April, 1662. The part he left was printed as *La Science universelle*, Paris, 1663, fol., 348 pages,—10 books containing about 11,000 lines. They begin with the nature of God, and end with the history of the fall of man. His verses, say Chaudon and Delandine, are perhaps the most nerveless, incorrect, obscure, and flat in French poetry; yet the author had been the friend of Molière, and had acted with him in comedy.

Louis Moréri (born 25th March, 1643, at Bargemont, in the diocese of Frejus, died 10th July, 1680, at Paris) wrote a dictionary of history, genealogy, and biography, *Le grand dictionnaire historique, ou le mélange curieux de l'histoire sacrée et profane*, Lyons, 1674, fol. He began a second edition on a larger scale, published at Lyons in 1681, in two volumes folio; the sixth edition was edited by Jean le Clerc, Amsterdam, 1691, fol. 4 vols.; the twentieth and last edition, Paris, 1759, fol. 10 vols. Moréri's dictionary, still very useful, was of very great value and importance, though not the first of the kind. It superseded the very inferior compilation of Juigné-Broissinère, *Dictionnaire Théologique, Historique, Poetique, Cosmographique, et Chronologique*, Paris, 1644, 4to; Rouen, 1668, etc.,—a translation, with additions, of the *Dictionarium Historicum, Geographicum, et Poeticum* of Charles Estienne, published in 1553, 4to, and often afterwards. As such a work was much wanted, Juigné's book went through twelve editions in less than thirty years, notwithstanding its want of criticism, errors, anachronisms, defects, and inferior style.

Johann Jacob Hofmann, born 11th September, 1635, died 10th March, 1706, son of a schoolmaster at Basel, which he is said never to have left, and where he was professor of Greek and History, wrote *Lexicon Universale Historico-Geographico-Chronologico-Poetico-Philologicum*, Basileæ, 1677, fol. 2 vols., 1823 pages, a dictionary of history, biography, geography, genealogies of princely families, chronology, mythology, and philology. At the end is Nomenclator Μιξόγλωττος, an index of names of places, people, etc., in many languages, carefully collected, and explained in Latin, filling 110 pages; with an index of subjects not forming separate articles, occupying 34 pages. In 1683 he published a continuation in 2 vols. fol., 2293 pages, containing, besides additions to the subjects given in his lexicon, the history of animals, plants, stones, metals, elements, stars, and especially of man and his affairs, arts, honors, laws, magic, music, rites, and a vast number of other subjects. In 1698 he published a second edition, Lugduni Batavorum, fol. 4 vols., 3742 pages, incorporating the continuation with additions. From the great extent of his plan, many articles, especially in history, are superficial and faulty.

Étienne Chauvin was born at Nismes 18th April, 1640. He fled to Rotterdam on the revocation of the Edict of Nantes, and in 1688 supplied Bayle's place in his lectures on philosophy. In 1695 he was invited by the elector of Brandenburg to go as professor of philosophy to Berlin, where he became the representative of the Cartesian philosophy, and died 6th April, 1725. He wrote *Lexicon Rationale, sive Thesaurus Philosophicus Ordine Alphabetico digestus*, Rotterdami, 1692, fol., 746 pages and 30 plates. An improved and enlarged edition was printed as *Lexicon philosophicum secundis curis*, Leovardiæ, 1713, large folio, 725 pages, and 30 plates. This great work may be considered as a dictionary of the Cartesian philosophy, and was very much used by Brucker and other earlier historians of philosophy. It is written in a very dry and scholastic style, and seldom names authorities.

The great dictionary of French, begun by the French Academy 7th February, 1639, excluded all words especially belonging to science and the arts. But the success of the rival dictionary of Furetière, which, as its title-page, as well as that of the *Essais* published in 1684, conspicuously announced, professed to give "les termes de toutes les Sciences et des Arts," induced Thomas Corneille, a member of the Academy, to compile *Le Dictionnaire des Arts et des Sciences*, which the Academy published with the first edition of their dictionary, Paris, 1694, folio, as a supplement in two volumes containing 1236 pages. It was reprinted at Amsterdam, 1696, fol. 2 vols., and at Paris in 1720, and again in 1732, revised by Fontenelle. A long series of dictionaries of arts and sciences have followed Corneille in placing in their titles the arts before the sciences, which he probably did merely in order to differ from Furetière. Corneille professed to quote no author whom he had not consulted; to take plants from Dioscorides and Mathiolus, medicine from Ettmüller, chemistry from a MS. of Perrault, and architecture, painting, and sculpture from Félibien; and to give an abridged history of animals, birds, and fishes, and an account of all religious and military orders and their statutes, heresiarchs and heresies, and dignities and charges ancient and modern.

Pierre Bayle (born 18th November, 1647, died 28th December, 1706) wrote a very important and valuable work, *Dictionnaire Historique et Critique*, Rotterdam, 1697, fol. 2 vols. His design was to make a dictionary of the errors and omissions of Moréri and others, but he was much embarrassed by the numerous editions and supplements of Moréri. A second edition with an additional volume appeared at Amsterdam, in 1702, fol. 3 vols. The fourth edition, Rotterdam, 1720, fol. 4 vols., was much enlarged from his manuscripts, and was edited by Prosper Marchand. It contains 3132 pages besides tables, etc. The ninth edition was published at Basel, 1741, fol. 10 vols. It was translated into English from the second edition, London, 1709, fol. 4 vols., with some slight additions and corrections by the author; and again from the fifth edition of 1730 by Birch and Lockman, London, 1734–40, fol. 5 vols. J. G. de Chaufepié published *Nouveau Dictionnaire historique*, Amsterdam, 1750–56, fol., 4 vols., as a supplement to Bayle. It chiefly consists of the articles added by the English translators, with many corrections and additions, and about 500 new articles added by himself, and contains in all about 1400 articles. Prosper Marchand, editor of the fourth edition, left at his death, 14th January, 1756, materials for a supplementary *Dictionnaire historique*, La Haye, 1758, fol. 2 vols. 891 pages, 136 articles. It had occupied his leisure moments for forty years. Much of his work was written on small scraps of paper, sometimes 20 in half a page and no larger than a nail, in such small characters that not only the editor but the printer had to use powerful magnifiers. Bayle's dictionary was also translated into German, Leipzig, 1741–44, fol. 4 vols., with a preface by J. C. Gottsched. It is still a work of great importance and value.

Vincenzo Maria Coronelli, a Franciscan friar, who was born in Venice about 1650, made cosmographer to the republic in 1685, became general of his order in 1702, and was found dead at his study table 9th December, 1718, began in 1701 to publish a general alphabetical encyclopædia, written in Italian, at which he had been working for thirty years, *Biblioteca Universale Sacro-profana*. It was to explain more than 300,000 words, to include history and biography as well as all other subjects, and to extend to 45 volumes folio. Volumes 1–39 were to contain the dictionary A to Z; 40, 41, the supplement; 42, retractations and corrections; 43, universal index; 44, index divided into matters; 45, index in various languages. But seven volumes only were published, Venezia, 1701–6, fol. 5609 pages, A to Caque. The first six volumes have each an index of from 28 to 48 pages (in all 224 pages) of subjects, whether forming articles or incidental. The articles in each are numbered, and amount to 30,269 in the six volumes, which complete the letter B. On an average 3 pages contain 22 articles. Each volume is dedicated to a different patron, —the pope, the doge, the king of Spain, etc. This work is remarkable for the extent and completeness of its plan, and for being the first great alphabetical encyclopædia, as well as for being written in a modern language, but it was hastily written and very incorrect. Never perhaps, says Tiraboschi (*Storia della Letteratura Italiana*, viii. 546), was there so quick a writer; he composed a folio volume as easily as others would a page, but he never perfected his works, and what we have of this book will not induce us to regret the want of the remainder.

The first alphabetical encyclopædia written in English was the work of a London clergyman, John Harris (born about 1667, elected first secretary of the Royal Society 30th November, 1709, died 7th September, 1719), *Lexicon Technicum, or an universal English Dictionary of Arts and Sciences*, London, 1704, fol. 1220 pages, 4 plates, with many diagrams and figures printed in the text. Like many subsequent English encyclopædias the pages are not numbered. It professes not merely to explain the terms used in the arts and sciences, but the arts and sciences themselves. The author complains that he found much less help from previous dictionaries than one would suppose, that Chauvin is full of obsolete school terms, and Corneille gives only bare explanations of terms, which often relate only to simple ideas and common things. He omits theology, antiquity, biography, and poetry; gives only technical history, geography, and chronology; and in logic, metaphysics, ethics, grammar, and rhetoric, merely explains the terms used. In mathematics and anatomy he professes to be very full, but says that the catalogues and places of the stars are very imperfect, as Flamsteed refused to assist him. In botany he gave from Ray, Morrison, and Tournefort "a pretty exact botanick lexicon, which was what we really wanted before," with an account of all the "kinds and subalternate species of plants, and their specific differences" on Ray's method. He gave a table of fossils from Dr. Woodward, professor of medicine in Gresham College, and took great pains to describe the parts of a ship accurately and particularly, going often on board himself for the purpose. In law he abridged from the best writers what he thought necessary. He meant to have given at the end an alphabet for each art and science, and some more plates of anatomy and ships, "but the undertaker could not afford it at the price." A review of his work extending to the unusual length of four pages, appeared in the *Philosophical Transactions*, 1704 (p. 1699). This volume was reprinted in 1708. A second volume of 1419 pages and 4 plates appeared in 1710, with a list of about 1300 subscribers. Great part of it consisted of mathematical and astronomical tables, as he intended his work to serve as a small mathematical library. He was allowed by Sir Isaac Newton to print his treatise on acids. He gives a table of logarithms to seven figures of decimals (44 pages), and one of sines, tangents, and secants (120 pages), a list of books filling two pages, and an index of the articles in both volumes under 26 heads, filling 50 pages. The longest lists are law (1700 articles), chyurgery, anatomy, geometry, fortification, botany, and music. The mathematical and physical part is considered very able. He often mentions his authorities, and gives lists of books on particular subjects, as botany and chronology. His dictionary was long very popular. The fifth edition was published in 1736, fol. 2 vols. A supplement, including no new subjects, appeared in 1744, London, fol. 996 pages, 6 plates. It was intended to rival Chambers, but, being considered a bookseller's speculation, was not well received.

Johann Hübner, rector of the Johanneum in Hamburg, born 17th March, 1668, wrote prefaces to two dictionaries written in German, which bore his name, and were long popular. The first was *Reales Staats-Zeitungs und Conversations-Lexicon*, Leipzig, 1704, 8vo; second edition, 1706, 947 pages; at the end a register of arms, and indexes of Latin and French words; fifth edition, 1711; fifteenth edition, 1735, 1119 pages. The thirty-first edition was edited and enlarged by F. A. Rüder, and published by Brockhaus, Leipzig, 1824–28, 8vo, 4 vols., 3088 pages. It was translated into Hungarian by Fejer, Pesten, 1816, 8vo, 5 vols., 2958 pages. The second, published as a supplement, was *Curieuses und reales Natur- Kunst- Berg- Gewerb- und Handlungs-Lexicon*, Leipzig, 1712, 8vo, 788 pages, frequently reprinted to 1792. The first relates to the political state of the world, as religion, orders, states, rivers, towns, castles, mountains, genealogy, war, ships; the second to nature, science, art, and commerce. They were the work of many authors, of whom Paul Jacob Marpurger, a celebrated and voluminous writer on trade and commerce, born at Nuremberg, 27th June, 1656, was an extensive contributor, and is the only one named by Hübner.

Johann Theodor Jablonski, who was born at Dantzic 15th December, 1654, appointed secretary to the newly founded Prussian Academy in 1700, when he went to Berlin, where he died 28th April, 1731, published *Allgemeines Lexicon der Künste und Wissenschaften*, Leipzig, 1721, 4to, a short but excellent encyclopædia still valued in Germany. It does not include theology, history, geography, biography, and genealogy. He not only names his authorities, but gives a list of their works. A new edition in 1748 was increased one-third to 1508 pages. An improved edition, Königsberg and Leipzig, 1767, 4to, 2 vols., 1852 pages, was edited by J. J. Schwabe, public teacher of philosophy at Leipsic.

Ephraim Chambers published his *Cyclopædia; or an Universal Dictionary of Arts and Sciences, containing an Explication of the Terms and an Account of the Things Signified thereby in the several Arts, Liberal and Mechanical, and the several Sciences, Human and Divine*, London, 1728, fol. 2 vols. The dedication to the king is dated October 15, 1727. Chambers endeavored to connect the scattered articles relating to each subject by a system of references, and to consider "the several matters, not only in themselves, but relatively, or as they respect each other; both to treat them as so many wholes and as so many parts of some greater whole." Under each article he refers to the subject to which it belongs, and also to its subordinate parts; thus Copyhold has a reference to Tenure, of which it is a particular kind, and other references to Rolls, Custom, Manor, Fine, Charterland, and Freehold. In his preface he gives an "analysis of the divisions of knowledge," 47 in number, with classed lists of the articles belonging to each, intended to serve as tables of contents and also as a rubric or directory indicating the order in which the articles should be read. But it does so very imperfectly, as the lists are curtailed by many *et cœteras*; thus 19 occur in a list of 119 articles under Anatomy, which has nearly 2200 articles in Rees's index. He omits etymologies unless "they appeared of some significance;" he gives only one grammatical form of each word, unless peculiar ideas are arbitrarily attached to different forms, as *precipitate, precipitant, precipitation*, when each has an article; and he omits complex ideas generally known, and thus "gets free of a vast load of plebeian words." His work, he says, is a collection, not the produce of one man's wit, for that would go but a little way, but of the whole commonwealth of learning. "Nobody that fell in my way has been spared, antient or modern, foreign nor domestic, Christian or Jew nor heathen." To the subjects given by Harris he adds theology, metaphysics, ethics, politics, logic, grammar, rhetoric, and poetry, but excludes history, biography, genealogy, geography, and chronology, except their technical parts. A second edition appeared in 1738, fol. 2 vols. 2466 pages, "retouched and amended in a thousand places." A few articles are added and some others enlarged, but he was prevented from doing more because "the booksellers were alarmed with a bill in parliament containing a clause to oblige the publishers of all improved editions of books to print their improvements separately. The bill after passing the Commons was unexpectedly thrown out by the Lords; but fearing that it might be revived, the booksellers thought it best to retreat though more than twenty sheets had been printed. Five other editions were published in London, 1739 to 1751–2, besides one in Dublin, 1742, all in 2 vols. fol. An Italian translation, Venezia, 1748–49, 4to, 9 vols., was the first complete Italian encyclopædia. When Chambers was in France in 1739 he rejected very favorable proposals to publish an edition there dedicated to Louis XV. His work was judiciously, honestly, and carefully done, and long maintained its popularity. But it had many defects and omissions, as he was well aware; and at his death, 15th May, 1740, he had collected and arranged materials for seven new volumes. John Lewis Scott was employed by the booksellers to select such articles as were fit for the press and to supply others. He is said to have done this very efficiently until appointed sub-preceptor to the prince of Wales and Prince Edward. His task was entrusted to Dr. (afterwards called Sir John) Hill, who performed it very hastily, and with characteristic carelessness and self-sufficiency, copying freely from his own writings. The *Supplement* was published in London, 1753, fol. 2 vols., 3307 pages and 12 plates. As Hill was a botanist, the botanical part which had been very defective in the *Cyclopædia* was the best. Abraham Rees published a revised and enlarged edition, "with the supplement and modern improvements incorporated in one alphabet," London, 1778–88, fol. 2 vols., 5010 pages, 159 plates. It was published in 418 numbers, at 6d. each Rees says that he has added more than 4400 new articles. At the end he gives an index of articles, classed under 100 heads, numbering about 57,000, and filling 80 pages. The heads, with 39 cross references, are arranged alphabetically. Rees's edition was reprinted, London, 1786–88, and 1789–91, fol. 5 vols., and Dublin, 1787, fol. 4 vols. According to the English custom, all the editions of the *Cyclopædia* have no pagination.

One of the largest and most comprehensive encyclopædias was undertaken and in a great measure completed by Johann Heinrich Zedler, a bookseller of Leipzig, who was born at Breslau, 7th January, 1706, made a Prussian commerzienrath in 1731, and died at Leipzig in 1760,—*Grosses vollständiges Universal Lexicon Aller Wissenschaften und Künste welche bishero durch menschlichen Verstand und Witz erfunden und verbessert worden*, Halle and Leipzig, 1732–50, fol. 64 vols. 64,309 pages; and *Nöthige Supplemente*, ib. 1751–54, vols. i. to iv., A to Caq, 3016 pages. The columns, two in a page, are numbered, varying from 1356 in vol. li. to 2588 in vol. xlix. Each volume has a dedication, with a portrait. The first nine are the emperor, the kings of Prussia and Poland, the empress of Russia, and the kings of England, France, Poland, Denmark, and Sweden. The dedications, of which two are in verse, and all are signed by Zedler, amount to 459 pages. The supplement has no dedications or portraits. The preface to the first volume of the work is by Johann Peter von Ludewig, chancellor of the university of Halle (born 15th August, 1690, died 6th September, 1743). Nine editors were employed, whom Ludewig compares to the nine muses; and the whole of each subject was entrusted to the same person, that all its parts might be uniformly treated. Carl Günther Ludovici (born at Leipzig 7th August, 1707, public teacher of philosophy there from 1734, died 3d July, 1778) edited the work from vol. xix., beginning the letter M, and published in 1739, to the end, and also the supplement. The work was published by subscription. Johann Heinrich Wolff, an eminent merchant and shop-keeper in Leipsic, born there 29th April, 1690, came to Zedler's assistance by advancing the very heavy expenses and becoming answerable for the subscriptions, and spared no cost that the work might be complete. Zedler very truly says, in his preface to vol. xviii., that his *Universal Lexicon* was a work such as no time and no nation could show, and both in its plan and execution it is much more comprehensive and complete than any previous encyclopædia. Colleges, says Ludewig, where all sciences are taught and studied, are on that account called *universities*, and their teaching is called *studium universale;* but the *Universal Lexicon* contains not only what they teach in theology, jurisprudence, medicine, philosophy, history, mathematics, etc., but also many other things belonging to courts, chanceries, hunting, forests, war and peace, and to artists, artisans, housekeepers, and merchants, not thought of in colleges. Its plan embraces not only history, geography, and biography, but also genealogy, topography, and from vol. xviii., published in 1738, lives of illustrious living persons. Zedler inquires why death alone should make a deserving man capable of having his services and worthy deeds made known to the world in print. The lives of the dead, he says, are to be found in books, but those of the living are not to be met with anywhere, and would often be more useful if known. In consequence of this preface, many lives and genealogies were sent to him for publication. Cross references generally give not only the article referred to, but also the volume and column, and, when necessary, such brief information as may distinguish the word referred to from others similar but of different meaning. Lists of authorities, often long, exact, and valuable, are frequently appended to the articles. This work, which is well and carefully compiled, and very trustworthy, is still a most valuable book of reference on many subjects, especially topography, genealogy, and biography. The genealogies and family histories are excellent, and many particulars are given of the lives and works of authors not easily found elsewhere.

A work on a new plan was published by Dennis de Coetlogon, a Frenchman naturalized in England, who styled himself "Knight of St. Lazare, M.D., and member of the Royal Academy of Angers,"—*An Universal History of Arts and Sciences*, London, 1745, fol. 2 vols., 2529 pages, 33 plates, and 161 articles arranged alphabetically. He "endeavors to render each treatise as complete as possible, avoiding above all things needless repetitions, and never puzzling the reader with the least reference." Theology is divided into several treatises; Philosophy into Ethicks, Logick, and Metaphysick, each under its letter; and Physick is subdivided into Anatomy, Botany, Geography, Geometry, etc. Military Art is divided into Army, Fortification, Gunnery. The royal license is dated 13th March, 1740–1, the dedication is to the duke of Gisors, the pages are numbered, there is an appendix of 35 pages of astronomical tables, and the two indexes, one to each volume, fill 69 pages, and contain about 9000 subjects. The type is large and the style diffuse, but the subject matter is sometimes curious. The author says that his work is the only one of the kind, and that he wrote out with his own hand every line, even the index. But notwithstanding the novelty of his plan, his work does not seem ever to have been popular.

Gianfrancesco Pivati, born at Padua in 1689, died at Venice in 1764, secretary of the Academy of Sciences at Venice, who had published in 1744 a 4to volume containing a *Dizionario universale*, wrote *Nuovo dizionario scientifico e curioso sacro-profano*, Venezia, 1746–51, fol. 10 vols., 7791 pages, 597 plates. It is a general encyclopædia, including geography, but not history or biography. He gives frequent references to his authorities and much curious information. His preliminary discourse (80 pages) contains a history of the several sciences from mathematics to geography. The book was published by subscription, and at the end of the last volume is a *Catalogo dei Signori Associati*, 252 in number, who took 266 copies. It is also remarkable for the number of its plates, which are engraved on copper. In each volume they are placed together at the end, and are preceded by an explanatory index of subjects referring to the plates and to the articles they illustrate.

One of the greatest and most remarkable literary enterprises of the 18th century, the famous French *Encyclopédie*, originated in a French translation of Chambers's *Cyclopædia*, begun in 1743, and finished in 1745 by John Mills, an Englishman resident in France, assisted by Gottfried Sellius, a very learned native of Dantzic, who, after being a professor at Halle and Göttingen, and residing in Holland, had settled in Paris. They applied to Lebreton, the king's printer, to publish the work, to fulfil the formalities required by French law, with which, as foreigners, they were not acquainted, and to solicit a royal privilege. This he obtained, but in his own name alone. Mills complained so loudly and bitterly of this deception that Lebreton had to acknowledge formally that the privilege belonged *en toute propriété* to John Mills. But, as he again took care not to acquaint Mills with the necessary legal formalities, this title soon became invalid. Mills then agreed to grant him part of his privilege, and in May, 1745, the work was announced as *Encyclopédié ou Dictionnaire Universel des Arts et des Sciences*, folio, four volumes of 250 to 260 sheets each, with a fifth of at least 120 plates, and a vocabulary or list of articles in French, Latin, German, Italian, and Spanish, with other lists for each language explained in French, so that foreigners might easily find any article wanted. It was to be published by subscription at 135 livres, but for large paper copies 200 livres, the first volume to be delivered in June, 1746, and the last two at the end of 1748. The subscription list, which was considerable, closed 31st December, 1745. Mills demanded an account, which Lebreton, who had again omitted certain formalities, insultingly refused. Mills brought an action against him, but before it was decided Lebreton procured the revocation of the privilege as informal, and obtained another for himself dated 21st January, 1746. Thus, for unwittingly contravening regulations with which his unscrupulous publisher ought to have made him acquainted, Mills was despoiled of the work he had both planned and executed, and had to return to England. Jean Paul de Gua de Malves, professor of philosophy in the college of France (born at Carcassonne in 1713, died 15th June, 1785), was then engaged as editor merely to correct errors and add new discoveries. But he proposed a thorough revision, and obtained the assistance of many learned men and artists, among whom Desessarts names Louis, Condillac, D'Alembert, and Diderot. But the publishers did not think his reputation high enough to ensure success, withheld their confidence, and often opposed his plans as too expensive. Tired at last of disputes, and too easily offended, De Gua resigned the editorship. The publishers, who had already made heavy advances, offered it to Diderot (born October, 1713, died 30th July, 1784), who was probably recommended to them by his very well received *Dictionnaire Universel de Medicine*, Paris, 1746–48, fol. 6 vols., published by Briasson, David, and Durand, with notes and additions by Julien Busson, doctor regent of the faculty of medicine of Paris. It was a translation, made with the assistance of Eidous and Toussaint, of the celebrated work of Dr. Robert James, inventor of the fever powders, *A Medicinal Dictionary*, London, 1743–45, fol. 3 vols., 3275 pages and 98 plates, comprising a history of drugs, with chemistry, botany, and natural history so far as they relate to medicine, and with an historical preface of 99 pages (in the translation 136). The proposed work was to have been similar in character. De Gua's papers were handed over to Diderot in great confusion. He soon persuaded the publishers to undertake a far more original and comprehensive work. His friend D'Alembert undertook to edit the mathematics. Other subjects were allotted to 21 contributors, each of whom received the articles on this subject in Mills's translation to serve as a basis for his work. But they were in most cases so badly composed and translated, so full of errors and omissions, that they were not used. The contributions were to be finished in three months, but none were ready in time, except Music by Rousseau, which he admits was hastily and badly done. Diderot was imprisoned at Vincennes, 29th July, 1749, for his *Lettre sur les Aveugles*. He was closely confined for 28 days, and was then for three months and ten days a prisoner on parole in the castle. This did not stop the printing, though it caused delay. The prospectus by Diderot appeared in November, 1750. The work was to form 8 vols. fol., with at least 600 plates. The first volume was published in July, 1751, and delivered to the subscribers in August. The second appeared in January, 1752. An *arrêt* of the council, 9th February, suppressed both volumes as injurious to the king's authority and to religion. Malesherbes, director-general of the Librairie, stopped the issue of volume ii., 9th February, and on the 21st went with a *lettre de cachet* to Lebreton's to seize the plates and the MSS., but did not find, says Barbier, even those of volume iii., as they had been taken to his own house by Diderot and one of the publishers. The Jesuits tried to continue the work, but in vain. It was less easy, says Grimm, than to ruin philosophers. The *Dictionnaire de Trévoux* pronounced the completion of the *Encyclopédie* impossible, and the project ridiculous (5th edition, 1752, iii. 750). The Government had to request the editors to resume the work as one honorable to the nation. The Marquis d'Argenson writes, 7th May, 1752, that Mme. de Pompadour had been urging them to proceed, and at the end of June he reports them as again at work. Volume iii., rather improved by the delay, appeared in October, 1753; and volume vii., completing G, in November, 1757. The clamors against the work soon recommenced. D'Alembert retired in January, 1758, weary of sermons, satires, and intolerant and absurd censors. The parliament of Paris, by an *arrêté*, 23d January, 1759, stopped the sale and distribution of the *Encyclopédie*, Helvetius's *De l'Esprit*, and six other books; and by an *arrêt*, 6th February, ordered them all to be burnt, but referred the *Encyclopédie* for examination to a commission of nine. An *arrêt du conseil*, 7th March, revoked the privilege of 1746, and stopped the printing. Volume viii. was then in the press. Malesherbes warned Diderot that he would have his papers seized next day; and when Diderot said he could not make a selection, or find a place of safety at such short notice, Malesherbes said, "Send them to me, they will not look for them there." This, according to Mme. de Vandeul, Diderot's daughter, was done with perfect success. In the article Pardonner Diderot refers to these persecutions, and says, "In the space of some months we have seen our honor, fortune, liberty, and life imperilled." Malesherbes, Choiseul, and Mme. de Pompadour protected the work; Diderot obtained private permission to go on printing, but with a strict charge not to publish any part until the whole was finished. The Jesuits were condemned by the parliament of Paris in 1762, and by the king in November, 1764. Volume i. of plates appeared in 1762, and volumes viii. to xvii., ten volumes of text, 9408 pages, completing the work, with the 4th volume of plates in 1765, when there were 4250 subscribers. The work circulated freely in the provinces and in foreign countries, and was secretly distributed in Paris and Versailles. The general assembly of the clergy, on 20th June, 1765, approved articles in which it was condemned, and on 27th September adopted a *mémoire* to be presented to the king. They were forbidden to publish their acts which favored the Jesuits, but Lebreton was required to give a list of his subscribers, and was put into the Bastille for eight days in 1766. A royal order was sent to the subscribers to deliver their copies to the lieutenant of police. Voltaire in 1774 relates that, at a *petit souper* of the king at Trianon, there was a debate on the composition of gunpowder. Mme. de Pompadour said she did not know how her rouge or her silk stockings were made. The Duc de la Vallière regretted that the king had confiscated their encyclopædias, which could decide everything. The king said he had been told that the work was most dangerous, but as he wished to judge for himself, he sent for a copy. Three servants with difficulty brought in the 21 volumes. The company found everything they looked for, and the king allowed the confiscated copies to be returned. Mme. de Pompadour died 15th April, 1764. Lebreton had half of the property in the work, and Durand, David, and Briasson had the rest. Lebreton, who had the largest printing office in Paris, employed 50 workmen in printing the last ten volumes. He had the articles set in type exactly as the authors sent them in, and when Diderot had corrected the last proof of each sheet, he and his foreman, hastily, secretly, and by night, unknown to his partners in the work, cut out whatever seemed to them daring, or likely to give offence, mutilated most of the best articles without any regard to the consecutiveness of what was left, and burnt the manuscript as they proceeded. The printing of the work was nearly finished when Diderot, having to consult one of his great philosophical articles in the letter S, found it entirely mutilated. He was confounded, says Grimm, at discovering the atrocity of the printer; all the best articles were in the same confusion. This discovery put him into a state of frenzy and despair from rage and grief. His daughter never heard him speak coolly on the subject, and after twenty years it still made him angry. He believed that every one knew as well as he did what was wanting in each article, but in fact the mutilation was not perceived even by the authors, and for many years was known to few persons. Diderot at first refused to correct the remaining proofs, or to do more than write the explanations of the plates. He required, according to Mme. de Vandeul, that a copy, now at St. Petersburg with his library, should be printed with columns in which all was restored. The mutilations began as far back as the article Intendant. But how far, says Rosenkrantz, this murderous, incredible, and infamous operation was carried cannot now be exactly ascertained. Diderot's articles, not including those on arts and trades, were reprinted in Naigeon's edition (Paris, 1821, 8vo, 22 vols.). They fill 4132 pages, and number 1139, of which 601 were written for the last ten volumes. They are on very many subjects, but principally on grammar, history, morality, philosophy, literature, and metaphysics. As a contributor, his special department of the work was philosophy, and arts and trades. He passed whole days in workshops, and began by examining a machine carefully, then he had it taken to pieces and put together again, then he watched it at work, and lastly worked it himself. He thus learned to use such complicated machines as the stocking and cut velvet looms. He at first received 1200 livres a year as editor, but afterwards 2500 livres a volume, besides a final sum of 20,000 livres. Although after his engagement he did not suffer from poverty as he had done before, he was obliged to sell his library in order to provide for his daughter. De Jaucourt spared neither time, trouble, nor expense in perfecting the work, for which he received nothing, and he employed several secretaries at it for ten years. To pay them he had to sell his house in Paris, which Lebreton bought with the profits derived from De Jaucourt's work. All the publishers made large fortunes; their expenses amounted to 1,158,000 livres, and their profits to 2,162,000. D'Alembert's "Discours Preliminaire," 45 pages, written in 1750, prefixed to the first volume, and delivered before the French Academy on his reception, 19th December, 1754, consists of a systematic arrangement of the various branches of knowledge, and an account of their progress since their revival. His system, chiefly taken from Bacon, divides them into three classes,—under memory, reason, and imagination. Arts and trades are placed under natural history, superstition and magic under science de Dieu, and orthography and heraldry under logic. The literary world is divided into three corresponding classes—*érudits*, *philosophes*, and *beaux esprits*. As in Chambers's *Cyclopædia*, history and biography were excluded, except incidentally; thus Aristotle's life is given in the article Aristotelisme. The science to which an article belongs is generally named at the beginning of it, references are given to other articles, and the author's names are marked by initials, of which lists are given in the earlier volumes, but sometimes their names are subscribed in full. Articles by Diderot have no mark, and those inserted by him as editor have an asterisk prefixed. Among the contributors were Voltaire, Euler, Marmontel, Montesquieu, D'Anville, D'Holbach, and Turgot, the leader of the new school of economists which made its first appearance in the pages of the *Encyclopédie*. Louis wrote the surgery, Daubenton natural history, Eidous heraldry and art, Toussaint jurisprudence, and Condamine articles on South America. No encyclopædia perhaps has been of such political importance, or has occupied so conspicuous a place in the civil and literary history of its century. It sought not only to give information, but to guide opinion. It was, as Rozenkrans says (*Diderot*, i. 157), theistic and heretical. It was opposed to the church, then all-powerful in France, and it treated dogma historically. It was, as Desnoiresterres says (*Voltaire*, v. 164), a war machine; as it progressed, its attacks both on the church and the still more despotic government, as well as on Christianity itself, became bolder and more undisguised, and it was met by opposition and persecution unparalleled in the history of encyclopædias. Its execution is very unequal, and its articles of very different value. It was not constructed on a regular plan, or subjected to sufficient supervision; articles were sent in by the contributors, and not seen by the editors until they were in type. In each subject there are some excellent articles, but others are very inferior or altogether omitted, and references are often given to articles which do not exist. Thus marine is said to be more than three-fourths deficient; and in geography errors and omissions abound,—even capitals and sovereign states are overlooked, while villages are given as towns, and towns are described which never existed. The style is too generally loose, digressive, and inexact; dates are seldom given; and discursiveness, verbosity, and dogmatism are frequent faults. Voltaire was constantly demanding truth, brevity, and method, and said it was built half of marble and half of wood. D'Alembert compared it to a harlequin's coat, in which there is some good stuff, but too many rags. Diderot was dissatisfied with it as a whole; much of it was compiled in haste; and carelessly written articles and incompetent contributors were admitted for want of money to pay good writers. Zedler's *Universal Lexicon* is now on the whole much more useful for reference than its far more brilliant successor. The permanent value of encyclopædias depends on the proportion of exact and precise facts they contain, and on their systematic regularity.

The first edition of the *Encyclopédie*, in 17 vols. folio, 16,288 pages, was imitated by a counterfeit edition printed at Geneva as the volumes appeared in Paris. Eleven folio volumes of plates were published at Paris, 1762 to 1772, containing 2888 plates and 923 pages of explanation, etc. A supplement was printed at Amsterdam and Paris, 1776–77, fol. 5 vols., 3874 pages, with 224 plates. History was introduced at the wish of the public, but only "the general features which mark epochs in the annals of the world." The astronomy was by Delalande, mathematics by Condorcet, tables by Bernouilli, natural history by Adanson, anatomy and physiology by Haller. Daubenton, Condamine, Marmontel, and other old contributors wrote many articles, and several were taken from foreign editions. A very full and elaborate index of the articles and subjects of the 33 volumes was printed at Amsterdam in 1780, fol. 2 vols. 1852 pages. It was made by Pierre Mouchon, who was born at Geneva 30th July, 1735, consecrated minister 18th August, 1758, pastor of the French church at Basel 1766, elected a pastor in Geneva 6th March, 1788, principal of the college there 22d April, 1791, died 20th August, 1797. This *Table Analytique* which took him five years to make, was undertaken for the publishers Cramer and De Tournes, who gave him 800 louis for it. Though very exact and full, he designedly omits the attacks on Christianity. This index was rendered more useful and indispensable by the very diffuse and digressive style of the work, and by the vast number of its articles. A complete copy of the first edition of the *Encyclopédie* consists of 35 vols. fol. printed 1751–80, containing 23,135 pages and 3132 plates. It was written by about 160 contributors. About 1761, Panckoucke and other publishers in Paris proposed a new and revised edition, and bought the plates for 250,000 livres. But, as Diderot indignantly refused to edit what he considered a fraud on the subscribers to the as yet unfinished work, they began simply to reprint the work, promising supplementary volumes. When three volumes were printed the whole was seized in 1770 by the Government at the complaint of the clergy, and was lodged in the Bastille. The plan of a second French edition was laid aside then, to be revived twenty years later in a very different form. Foreign editions of the *Encyclopédie* are numerous, and it is difficult to enumerate them correctly. One, with notes by Ottavio Diodati, Dr. Sebastiano Paoli, and Carlo Giuliani appeared at Lucca, 1758–71, fol. 17 vols. of text and 10 of plates. Though it was very much expurgated, all engaged in it were excommunicated by the pope in 1759. An attempt made at Siena to publish an Italian translation failed. An edition by the Abbé Serafini and Dr. Gonnella, Livourne, 1770, etc., fol. 33 vols., returned a profit of 60,000 piastres, and was protected by Leopold II., who secured the pope's silence. Other editions are Genève, Cramer, 1772–76, a fac-simile reprint; Genève, Pellet, 1777–79, 4to, 36 vols. of text and 3 of plates, with 6 vols. of Mouchon's index, Lyon, 1780, 4to; Genève et Neufchâtel, Pellet, 1778–79, 4to, 36 vols. of text, and 3 of plates; Lausanne, 1778–81, 36 vols. 4to, or 72 octavo, of text and 3 of plates 1779–80; Lausanne et Berne, chez les Sociétés Typographiques, 1780–82, 36 vols. 8vo of text and 3 vols. 4to of plates, 1782. These four editions have the supplement incorporated. Fortuné Barthelemy de Felice, an Italian monk, born at Rome 24th August, 1723, who had been professor at Rome and Naples, and had become a Protestant, printed a very incorrect though successful edition, Yverdun, 1770–80, 4to, 42 vols. of text, 5 of supplement, and 10 of plates. It professed to be a new work, standing in the same relationship to the *Encyclopédie* as that did to Chambers's, which is far from being the case. Sir Joseph Ayloffe issued proposals, 14th December, 1751, for an English translation of the *Encyclopédie*, to be finished by Christmas, 1756, in 10 vols. 4to, with at least 600 plates. No. 1 appeared in January, 1752, but met with little success. Several selections of articles and extracts have been published under the title of *L'Esprit de l'Encyclopédie*. The last was by Hennequin, Paris, 1822–23, 8vo, 15 vols. An English selection is *Select Essays from the Encyclopedy*, London, 1773, 8vo. The articles of most of the principal contributors have been reprinted in the editions of their respective works. Voltaire wrote 8 vols. 8vo of a kind of fragmentary supplement, *Questions sur l'Encyclopédie*, frequently printed, and usually included in editions of his works, together with his contributions to the *Encyclopédie* and his *Dictionnaire Philosophique*. Several special dictionaries have been formed from the *Encyclopédie*, as the *Dictionnaire Portatif des Arts et Métiers*, Paris, 1766, 8vo, 2 vols., about 1300 pages, by Philippe Macquer, brother of the author of the *Dict. de Chimie*. An enlarged edition by the Abbé Jaubert, Paris, 1773, 5 vols. 8vo, 3017 pages, was much valued and often reprinted. The books attacking and defending the *Encyclopédie* are very many. No original work of the 18th century, says Lanfrey, has been more depreciated, ridiculed, and calumniated. It has been called chaos, nothingness, the Tower of Babel, a work of disorder and destruction, the gospel of Satan, and even the ruins of Palmyra.

The *Encyclopædia Britannica*, "by a society of gentlemen in Scotland, printed in Edinburgh for A. Bell and C. Macfarquhar, and sold by Colin Macfarquhar at his printing office in Nicolson Street," was completed in 1771 in 3 volumes, 4to, containing 2670 pages and 160 copperplates, engraved by Andrew Bell. It was published in numbers, of which the first two were issued in December, 1768, "price 6d. each, or 8d. on a finer paper," and was to be completed in 100 weekly numbers. It was compiled, as the title-page says, on a new plan. The different sciences and arts were "digested into distinct treatises or systems," of which there are 45 with cross headings, that is, titles printed across the page, and about 30 other articles more than three pages long. The longest are "Anatomy," 166 pages, and "Surgery," 238 pages. "The various technical terms, etc., are explained as they occur in the order of the alphabet." "Instead of dismembering the sciences, by attempting to treat them intelligibly under a multitude of technical terms, they have digested the principles of every science in the form of systems or distinct treatises, and explained the terms as they occur in the order of the alphabet, with references to the sciences to which they belong." This plan, as the compilers say, differs from that of all the previous dictionaries of arts and sciences. Its merit and novelty consist in the combination of De Coetlogon's plan with that in common use,—on the one hand keeping important subjects together, and on the other facilitating reference by numerous separate articles. It is doubtful to whom the credit of this plan is due. The editor, William Smellie, a printer (born in 1740, died 24th June, 1795), afterwards secretary and superintendent of natural history to the Society of Scottish Antiquaries, is said by his biographer to have devised the plan and written or compiled all the chief articles. And he prints, but without date, part of a letter written and signed by Andrew Bell, by which he was engaged in the work :—"Sir, As we are engaged in publishing a dictionary of the arts and sciences, and as you have informed us that there are fifteen capital sciences which you will undertake for and write up the sub-divisions and detached parts of these conformable to your plan, and likewise to prepare the whole work for the press, etc., etc., we hereby agree to allow you £200 for your trouble," etc. Prof. Macvey Napier says that Smellie "was more likely to have suggested that great improvement than any of his known coadjutors." Archibald Constable, who was interested in the work from 1788, and was afterwards intimately acquainted with Bell, says Colin Macfarquhar was the actual projector of the *Encyclopædia*, and the editor of the first two editions, while Smellie was merely "a contributor for hire" (*Memoirs*, ii. 311). Dr. Gleig, in his preface to the third edition, says, "The idea had been conceived by him (Colin Macfarquhar) and his friend Mr. Andrew Bell, engraver. By whom these gentlemen were assisted in digesting the plan which attracted to that work so much public attention, or whether they had any assistance, are questions in which our readers cannot be interested." Macfarquhar, according to Constable, was a person of excellent taste and very general knowledge, though at starting he had little or no capital, and was obliged to associate Bell, then the principal engraver in Edinburgh, as a partner in his undertaking.

The second edition was begun in 1776, and was published in numbers, of which the first was issued 21st June, 1777, and the last, No. 181, 18th September, 1784, forming 10 vols. 4to, dated 1778 to 1783, and containing 8595 pages and 340 plates. The pagination is continuous, ending with page 9200, but 295 pages are inserted in various places, and page 7099 is followed by 8000. The number and length of the articles was much increased, 72 have cross headings, and more than 150 others may be classed as long articles. At the end is an appendix ("Abatement" to "Wood") of 200 pages, containing under the heading Botanical Table, a list of the 931 genera included in the 58 natural orders of Linnæus, and followed by a list of 526 books, said to have been the principal authorities used. All the maps are placed together under the article "Geography" (195 pages). Most of the long articles have numbered marginal titles; "Scotland," 84 pages, has 837. "Medicine," 309 pages, and "Pharmacy" have each an index. The plan of the work was enlarged by the addition of history and biography, which encyclopædias in general had long omitted. "From the time of the second edition of this work, every cyclopædia of note, in England and elsewhere, has been a cyclopædia not solely of arts and sciences, but of the whole wide circle of general learning and miscellaneous information" (*Quarterly Review*, cxiii. 362). Smellie was applied to by Bell to edit the second edition, and to take a share of one-third in the work; but he refused, because the other persons concerned in it, at the suggestion of "a very distinguished nobleman of very high rank" (said by Professor Napier to have been the duke of Buccleuch), insisted upon the introduction of a system of general biography, which he considered inconsistent with the character of a dictionary of arts and sciences. James Tytler, M.A., seems to have been selected as the next most eligible compiler. His father, a man of extensive knowledge, was 53 years minister of Fearn in Forfarshire, and died in 1785. Tytler (outlawed by the High Court of Justiciary, 7th January, 1793, buried at Salem in Massachusetts 11th January, 1804, aged fifty-eight) "wrote," says Watt, "many of the scientific treatises and histories, and almost all the minor articles" (*Bibliotheca Brit.*).

After about a year's preparation, the third edition was announced in 1787; the first number was published early in 1788, and the first volume in October, 1788. There were to be 300 weekly numbers, price 1s. each, forming 30 parts at 10s. 6d. each, and 15 volumes, with 360 plates. It was completed in 1797 in 18 vols. 4to, containing 14,579 pages and 542 plates. Among the multifarious articles represented in the frontispiece, which was required by the traditional fashion of the period, is a balloon. The maps are, as in subsequent editions, distributed among the articles relating to the respective countries. It was edited by Colin Macfarquhar, as far as the article "Mysteries" (by Dr. Doig, vol. xii.), when he died, 2d April, 1793, in his forty-eighth year, "worn out," says Constable, "by fatigue and anxiety of mind." His children's trustees and Andrew Bell requested George Gleig of Stirling (consecrated 30th October, 1808, assistant and successor to the bishop of Brechin), who had written about twelve articles, to edit the rest of the work; "and for the time, and the limited sum allowed him for the reward of contributors, his part in the work was considered very well done" (Constable, ii. 312). Professor Robison was induced by Gleig to become a contributor. He first revised the article "Optics," and then wrote a series of articles on natural philosophy, which attracted great attention and were long highly esteemed by scientific men. The sub-editors were James Walker (Primus Scotiæ Episcopus, 27th May, 1837, died 5th March, 1841, aged seventy) until 1795, then James Thomson, succeeded in November, 1796, by his brother Thomas, afterwards professor of chemistry at Glasgow, who remained connected with the *Encyclopædia* until 1800. According to Kerr (*Smellie's Life*, i. 364–5), 10,000 copies were printed, and the profit to the proprietors was £42,000, besides the payments for their respective work in the conduct of the publication as tradesmen,—Bell as engraver of all the plates, and Macfarquhar as sole printer. According to Constable (*Memoirs*, ii. 312), the impression was begun at 5000 copies, and concluded with a sale of 13,000. James Hunter, "an active bookseller of no character," who had a shop in Middle Row, Holburn, sold the book to the trade, and on his failure Thomson Bonar, a wine merchant, who had married Bell's daughter, became the seller of the book. He quarrelled with his father-in-law, who would not see him for ten years before his death in 1809. When the edition was completed, the copyright and remaining books were sold in order to wind up the concern, and "the whole was purchased by Bell, who gave £13 a copy, sold all the complete copies to the trade, printed up the odd volumes, and thus kept the work in the market for several years" (Constable, ii. 312).

The supplement of the third edition, printed for Thomson Bonar, and edited by Gleig, was published in 1801 in 2 vols. 4to, containing 1624 pages and 50 copperplates engraved by D. Lizars. In the dedication to the king, dated Stirling, 10th December, 1800, Dr. Gleig says: "The French *Encyclopédie* had been accused, and justly accused, of having disseminated far and wide the seeds of anarchy and atheism. If the *Encyclopædia Britannica* shall in any degree counteract the tendency of that pestiferous work, even these two volumes will not be wholly unworthy of your Majesty's attention." Professor Robison added 19 articles to the series he had begun when the third edition was so far advanced. Professor Playfair assisted in "Mathematics." Dr. Thomas Thomson wrote "Chemistry," "Mineralogy," and other articles, in which the use of symbols was for the first time introduced into chemistry; and these articles formed the first outline of his *System of Chemistry*, published at Edinburgh in 1802, 8vo, 4 vols.; the sixth edition, 1821.

The fourth edition, printed for Andrew Bell, was begun in 1800 or 1801, and finished in 1810 in 20 vols. 4to, containing 16,033 pages, with 581 plates engraved by Bell. The dedication to the king, signed Andrew Bell, is dated Lauristoun, Edinburgh, 1809. The preface is that of the third edition with the necessary alterations and additions in the latter part. No articles were reprinted from the supplement, as Bell had not the copyright. Professor Wallace's articles on Mathematics were much valued, and raised the scientific character of the work. Dr. Thomas Thomson declined the editorship, and recommended Dr. James Millar, afterwards editor of the *Encyclopædia Edinensis* (died 13th July, 1827). He was fond of natural history and a good chemist, but according to Constable, slow and dilatory and not well qualified. Andrew Bell died 10th June, 1809, aged eighty-three, "leaving," says Constable, "two sets of trustees, one literary to make the money, the other legal to lay it out after it was made." The edition began with 1250 copies and concluded at 4000, of which two-thirds passed through the hands of Constable's firm. Early in 1804 Andrew Bell had offered Constable and his partner Hunter the copyright of the work, printing materials, etc., and all that was then printed of the fourth edition, for £20,000. This offer was in agitation in March, 1804, when the two partners were in London. On 5th May, 1804, after Lord Jeffrey's arrival in Edinburgh, as he relates to Francis Horner, they intrusted him with a design, on which he found that most of his friends had embarked with great eagerness, "for publishing an entire new encyclopædia upon an improved plan. Stewart, I understand, is to lend his name, and to write the preliminary discourse, besides other articles. Playfair is to superintend the mathematical department, and Robison the natural philosophy. Thomas Thomson is extremely zealous in the cause. W. Scott has embraced it with great affection. . . . The authors are to be paid at least as well as reviewers, and are to retain the copyright of their articles for separate publication if they think proper." (Cockburn, *Life of Lord Jeffrey*, 1852, ii. 90.) It was then, perhaps, that Constable gave £100 to Bonar for the copyright of the supplement.

The fifth edition was begun immediately after the fourth as a mere reprint. "The management of the edition, or rather mismanagement, went on under the *lawyer trustees* for several years, and at last the whole property was again brought to the market by public sale. There were about 1800 copies printed of the first five volumes, which formed one lot, the copyright formed another lot, and so on. The whole was purchased by myself and in my name for between £13,000 and £14,000, and it was said by the wise booksellers of Edinburgh and others that I had completely ruined myself and all connected with me by a purchase to such an enormous amount; this was early in 1812" (Constable, ii. 314). Bonar, who lived next door to the printing office, thought he could conduct the book, and had resolved on the purchase. Having a good deal of money, he seemed to Constable a formidable rival, whose alliance was to be secured. After "sundry interviews" it was agreed that Constable should buy the copyright in his own name, and that Bonar should have one-third, and also one-third of the copyright of the supplement, for which he gave £200. Dr. James Millar corrected and revised the last 15 volumes. The preface is dated 1st December, 1814. The printing was superintended by Bonar, who died 26th July, 1814. His trustees were repaid his advances on the work, about £6000, and the copyright was valued at £11,000, of which they received one-third, Constable adding £500, as the book had been so extremely successful. It was published in 20 vols., 16,017 pages, 582 plates, price £36, and dated 1817.

Soon after the purchase of the copyright, Constable began to prepare for the publication of a supplement, to be of four or, at the very utmost, five volumes. "The first article arranged for was one on 'Chemistry' by Sir Humphry Davy, but he went abroad [in October, 1813] and I released him from his engagement, and employed Mr. Brande; the second article was Mr. Stewart's Dissertation, for which I agreed to pay him £1000, leaving the extent of it to himself, but with this understanding, that it was not to be under ten sheets, and might extend to twenty" (Constable, ii. 318). Dugald Stewart, in a letter to Constable, 15th November, 1812, though he declines to engage to execute any of his own suggestions, recommends that four discourses should "stand in front," forming "a general map of the various departments of human knowledge," similar to "the excellent discourse prefixed by D'Alembert to the French *Encyclopédie*," together with historical sketches of the progress since Bacon's time of modern discoveries in metaphysical, moral, and political philosophy, in mathematics and physics, in chemistry, and in zoology, botany, and mineralogy. He would only promise to undertake the general map and the first historical sketch, if his health and other engagements permitted, after the second volume of his *Philosophy of the Human Mind* (published in 1813) had gone to press. For the second he recommended Playfair, for chemistry Sir Humphry Davy. He received £1000 for the first part of his dissertation (166 pages), and £700 for the second (257 pages), the right of publication being limited to the Supplement and *Encyclopædia*. Constable next contracted with Professor Playfair for a dissertation "to be equal in length or not to Mr. Stewart's, for £250; but a short time afterwards I felt that to pay one eminent individual £1000 because he would not take less would be quite unfair, and I wrote to the worthy Professor that I had fixed his payment at £500." Constable gave him £500 for the first part (127 pages), and would have given as much for the second (90 pages) if it had been as long. His next object was to find out the greatest defects in the book, and he gave Professor Leslie £200 and Graham Dalyell £100 for looking over it. He then wrote out a prospectus and submitted it in print to Stewart, "but the cautious philosopher referred" him to Playfair, who "returned it next day very greatly improved." For this Constable sent him six dozen of very fine old sherry, only feeling regret that he had nothing better to offer. He at first intended to have two editors, "one for the strictly literary and the other for the scientific department." He applied to Dr. Thomas Brown, who "preferred writing trash of poetry to useful and lucrative employment." At last he fixed on Mr. Macvey Napier (born 1777), whom he had known from 1798, and who "had been a hard student, and at college laid a good foundation for his future career, though more perhaps in general information than in what would be, strictly speaking, called scholarship; this, however, does not fit him the less for his present task." Constable, in a letter dated 11th June, 1813, offered him £300 before the first part went to press, £150 on the completion at press of each of the eight half volumes, £500 if the work was reprinted or extended beyond 7000 copies, and £200 for incidental expenses. "In this way the composition of the four volumes, including the introductory dissertations, will amount to considerably more than £9000." In a postscript the certain payment is characteristically increased to £1575, the contingent to £735, and the allowance for incidental expenses to £300 (Constable, ii. 326). Napier went to London, and obtained the co-operation of many literary men. The supplement was published in half-volume parts from December, 1816, to April, 1824. It formed six volumes 4to, containing 4933 pages, 125 plates, 9 maps, three dissertations, and 669 articles, of which a list is given at the end. The first dissertation, on the "progress of metaphysical, ethical, and political philosophy," was by Stewart, who completed his plan only in respect to metaphysics. He had thought it would be easy to adapt the intellectual map or general survey of human knowledge, sketched by Bacon and improved by D'Alembert, to the advanced state of the sciences, while its unrivalled authority would have softened criticism. But on closer examination he found the logical views on which this systematic arrangement was based essentially erroneous; and, doubting whether the time had come for a successful repetition of this bold experiment, he forbore to substitute a new scheme of his own. Sir James Mackintosh characterized this discourse as "the most splendid of Mr. Stewart's works, a composition which no other living writer of English prose has equalled" (*Edinburgh Review*, xxvii. 191, September, 1816). The second dissertation, "On the progress of mathematics and physics," was by Playfair, who died 19th July, 1819, when he had only finished the period of Newton and Leibnitz. The third, by Professor Brande, "On the progress of chemistry from the early Middle Ages to 1800," was the only one completed. These historical dissertations were admirable and delightful compositions, and important and interesting additions to the *Encyclopædia*; but it is difficult to see why they should form a separate department distinct from the general alphabet. The preface, dated March, 1824, begins with an account of the more important previous encyclopædias, relates the history of this to the sixth edition, describes the preparation for the supplement and gives an "outline of the contents," and mentions under each great division of knowledge the principal articles and their authors' names, often with remarks on the characters of both. Among the distinguished contributors were Leslie, Playfair, Ivory, Sir John Barrow, Tredgold, Jeffrey, John Bird Sumner, Blanco White, Hamilton Smith, and Hazlitt. Sir Walter Scott, to gratify his generous friend Constable, laid aside *Waverley*, which he was completing for publication, and in April and May, 1814, wrote "Chivalry." He also wrote "Drama" in November, 1818, and "Romance" in the summer of 1823. As it seemed to the editor that encyclopædias had previously attended little to political philosophy, he wrote "Balance of Power," and procured from James Mill "Banks for Savings," "Education," "Law of Nations," "Liberty of the Press," and other articles, which, reprinted cheaply, had a wide circulation. M'Culloch wrote "Corn Laws," "Interest," "Money," "Political Economy," etc. Mr. Ricardo wrote "Commerce" and "Funding System," and Professor Malthus, in his article "Population," gave a comprehensive summary of the facts and reasonings on which his theory rested. In the article "Egypt," Dr. Thomas Young "first gave to the public an extended view of the results of his successful interpretation of the hieroglyphic characters on the stone of Rosetta," with a vocabulary of 221 words in English, Coptic, Hieroglyphic, and Enchorial, engraved on four plates. There were about 160 biographies, chiefly of persons who had died within the preceding 30 years. Constable "wished short biographical notices of the first founders of this great work, but they were, in the opinion of my editor, too insignificant to entitle them to the rank which such separate notice, it was supposed, would have given them as literary men, although his own consequence in the world had its origin in their exertions" (*Memoirs*, ii. 326). It is to be regretted that this wish was not carried out, as was done in the latter volumes of Zedler. Arago wrote "Double Refraction" and "Polarization of Light," a note to which mentions his name as author. Playfair wrote "Æpinus," and "Physical Astronomy." Biot wrote "Electricity" and "Pendulum." He "gave his assistance with alacrity," though his articles had to be translated. Signatures, on the plan of the *Encyclopédie*, were annexed to each article, the list forming a triple alphabet, A to XXX, with the full names of the 72 contributors arranged apparently in the order of their first occurrence. At the end of vol. vi. are Addenda and Corrigenda, including "Interpolation," by Leslie, and "Polarization of Light," by Arago.

The sixth edition, "revised, corrected, and improved," appeared in half volume parts, price 16s. in boards, vol. xx. part ii. completing the work in May, 1823. Constable, thinking it not wise to reprint so large a book year after year without correction. in 1820 selected Mr. Charles Maclaren (born 7th October, 1782) as editor. "His attention was chiefly directed to the historical and geographical articles. He was to keep the press going, and have the whole completed in three years." He wrote "America," "Greece," "Troy," etc. Many of the large articles, as "Agriculture," "Chemistry," "Conchology," were new or nearly so; and references were given to the supplement. A new edition in 25 vols. was contemplated, not to be announced till a certain time after the supplement was finished; but Constable's house stopped payment 19th January, 1826, and his copyrights were sold by auction. Those of the *Encyclopædia* were bought by contract, 16th July, 1828, for £6150, by Thomas Allan, proprietor of the *Caledonian Mercury*, Adam Black, Abram Thomson, bookbinder, and Alexander Wight, banker, who, with the trustee of Constable's estate, had previously begun the seventh edition. Not many years later Mr. Black purchased all the shares and became sole proprietor.

The seventh edition, 21 vols. 4to (with an index of 187 pages, compiled by Robert Cox), containing 17,101 pages and 506 plates, edited by Macvey Napier, assisted by James Browne, LL.D., was begun in 1827, and published from March, 1830, to January, 1842. It was reset throughout and stereotyped. Mathematical diagrams were printed in the text from woodcuts. The first half of the preface was nearly that of the supplement. The list of signatures, containing 167 names, consists of four alphabets with additions, and differs altogether from that in the supplement; many names are omitted, the order is changed. and 103 are added. A list follows of over 300 articles, without signatures, by 87 writers. The dissertations—1st, Stewart's, 289 pages; 2d, "Ethics" (136 pages), by Sir James Mackintosh, whose death prevented the addition of "Political Philosophy;" 3d, Playfair's, 139 pages; 4th, its continuation by Sir John Leslie, 100 pages—and their index of 30 pages, fill vol. i. As they did not include Greek philosophy, "Aristotle," "Plato," and "Socrates" were supplied by Dr. Hampden, afterwards bishop of Hereford. Among the numerous contributors of eminence, mention may be made of Sir David Brewster, Prof. Phillips, Prof. Spalding, John Hill Burton, Thomas De Quincey, Patrick Fraser Tytler, Captain Basil Hall, Sir Thomas Dick Lauder, Antonio Panizzi, John Scott Russell, and Robert Stephenson. Zoology was divided into 11 chief articles, "Mammalia," "Ornithology," "Reptilia," "Ichthyology," "Mollusca," "Crustacea," "Arachnides," "Entomology," "Helminthology," "Zoophytes," and "Animalcule,"—all by James Wilson. The biographical articles, in this as in all the editions of the *Encyclopædia*, do not embrace the names of persons living at the time of publication.

The eighth edition, 1853–60, 4to, 21 vols. (and index of 239 pages, 1861), containing 17,957 pages and 402 plates, with many woodcuts, was edited by Dr. Thomas Stewart Traill, professor of medical jurisprudence in Edinburgh University. The dissertations were reprinted, with one on the "Rise, Progress, and Corruptions of Christianity" (97 pages), by Archbishop Whately, and a continuation of Leslie's to 1850, by Professor James David Forbes, 198 pages, the work of nearly three years, called by himself his "magnum opus" (*Life*, pp. 361, 366). Lord Macaulay, Charles Kingsley, Isaac Taylor, Hepworth Dixon, Robert Chambers, Rev. Charles Merivale, Rev. F. W. Farrar, Sir John Richardson, Dr. Scoresby, Dr. Hooker, Henry Austin Layard, Edward B. Eastwick, John Crawfurd, Augustus Petermann, Baron Bunsen, Sir John Herschel, Dr. Lankester, Professors Owen, Rankine, William Thomson, Aytoun, Blackie, Daniel Wilson, and Jukes, were some of the many eminent new contributors found among the 344 authors, of whom an alphabetical list is given, with a key to the signatures. In the preface a list of 279 articles by 189 writers, classed under 15 heads, is given, instead of the enumeration of the chief articles and their writers, with critical remarks and explanations, inserted in previous prefaces. It is very much clearer and more useful, though its tabular form excluded all particulars except in notes. This edition was not wholly reset like the seventh, but many long articles were retained almost or entirely intact.

The publication of the ninth edition (the present work) was commenced in January, 1875.

A new and enlarged edition of the *Encyclopédie* arranged as a system of separate dictionaries, and entitled *Encyclopédie Méthodique ou par ordre de matières*, was undertaken by Charles Joseph Panckoucke, a publisher of Paris (born at Lille 26th November, 1736, died 19th December, 1798). His privilege was dated 20th June, 1780. The articles belonging to different subjects would readily form distinct dictionaries, although, having been constructed for an alphabetical plan, they seemed unsuited for any system wholly methodical. Two copies of the book and its supplement were cut up into articles, which were sorted into subjects. The division adopted was,—1, mathematics; 2, physics; 3, medicine; 4, anatomy and physiology; 5, surgery; 6, chemistry, metallurgy, and pharmacy; 7, agriculture; 8, natural history of animals, in six parts; 9, botany; 10, minerals; 11, physical geography; 12, ancient and modern geography; 13, antiquities; 14, history; 15, theology; 16, philosophy; 17, metaphysics, logic, and morality; 18, grammar and literature; 19, law; 20, finance; 21, political economy; 22, commerce; 23, marine; 24, art militaire; 25, beaux arts; 26, arts et métiers,—all forming distinct dictionaries entrusted to different editors. The first object of each editor was to exclude all articles belonging to other subjects, and to take care that those of a doubtful nature should not be omitted by all. In some words (such as air, which belonged equally to chemistry, physics, and medicine) the methodical arrangement has the unexpected effect of breaking up the single article into several widely separated. Each dictionary was to have an introduction and a classified table of the principal articles. History and its minor parts, as inscriptions, fables, medals, were to be included. Theology, which was neither complete, exact, nor orthodox, was to be by the Abbé Bergier, confessor to Monsieur. The whole work was to be completed and connected together by a Vocabulaire Universel, 1 vol. 4to, with references to all the places where each word occurred, and a very exact history of the *Encyclopédie* and its editions by Panckoucke. The prospectus, issued early in 1782, proposed three editions—84 vols. 8vo, 43 vols. 4to with 3 columns to a page, and 53 vols. 4to of about 100 sheets with 2 columns to a page, each edition having 7 vols. 4to of 250 to 300 plates each. The subscription was to be 672 livres from 15th March to July, 1782, then 751, and 888 after April, 1783. It was to be issued in livraisons of 2 vols. each, the first (jurisprudence, vol. i., literature, vol. i.) to appear in July, 1782, and the whole to be finished in 1787. The number of subscribers, 4072, was so great that the subscription list of 672 livres was closed 30th April. Twenty-five printing offices were employed, and in November, 1782, the 1st livraison (jurisprudence, vol. i., and half vol. each of arts et métiers and histoire naturelle) was issued. A Spanish prospectus was sent out, and obtained 330 Spanish subscribers, with the inquisitor-general at their head. The complaints of the subscribers and his own heavy advances, over 150,000 livres, induced Panckoucke, in November, 1788, to appeal to the authors to finish the work. Those *en retard* made new contracts, giving their word of honor to put their parts to press in 1788, and to continue them without interruption, so that Panckoucke hoped to finish the whole, including the vocabulary (4 or 5 vols.), in 1792. Whole sciences, as architecture, engineering, hunting, police, games, etc., had been overlooked in the prospectus; a new division was made in 44 parts, to contain 51 dictionaries and about 124 vols. Permission was obtained, 27th February, 1789, to receive subscriptions for the separate dictionaries. Two thousand subscribers were lost by the Revolution. The 50th livraison appeared on July 23, 1792, when all the dictionaries eventually published had been begun except seven—jeux familiers and mathematiques, physics, art oratoire, physical geography, chasses, and pêches: and 18 were finished,—mathematics, games, surgery, ancient and modern geography, history, theology, logic, grammar, jurisprudence, finance, political economy, commerce, marine, arts militaires, arts académiques, arts et métiers, encyclopædiana. Supplements were added to military art in 1797, and to history in 1807, but not to any of the other 16, though required for most long before 1832. The publication was continued by Henri Agasse, Panckoucke's son-in-law, from 1794 to 1813, and then by Mme. Agasse, his widow, to 1832, when it was completed in 102 livraisons or 337 parts, forming 166½ vols. of text, and 51 parts containing 6439 plates. The letterpress issued with the plates amounts to 5458 pages, making with the text 124,210 pages. To save expense the plates belonging to architecture were not published. Pharmacy (separated from chemistry), minerals, education, ponts et chaussées had been announced, but were not published, neither was the Vocabulaire Universel, the key and index to the whole work, so that it is difficult to carry out any research, or to find all the articles on any subject. The original parts have been so often subdivided, and have been so added to by other dictionaries, supplements, and appendices, that, without going into great detail, an exact account cannot be given of the work, which contains 88 alphabets, with 83 indexes, and 166 introductions, discourses, prefaces, etc. Many dictionaries have a classed index of articles; that of économic politique is very excellent, giving the contents of each article, so that any passage can be found easily. The largest dictionaries are medicine, 13 vols., 10,330 pages; zoology, 7 dictionaries, 13,645 pages, 1206 plates; botany, 12,002 pages, 1000 plates (34 only of cryptogamic plants); geography, 3 dictionaries and 2 atlases, 9090 pages 193 maps and plates; jurisprudence (with police and municipalities), 10 vols., 7607 pages. Anatomy, 4 vols., 2866 pages, is not a dictionary but a series of systematic treatises. Assemblée Nationale was to be in three parts,—(1) the history of the Revolution, (2) debates, and (3) laws and decrees. Only vol. ii., debates, appeared, 1792, 804 pages, Absens to Aurillac. Ten volumes of a Spanish translation with a vol. of plates were published at Madrid to 1806,—viz., historia natural, i., ii.; grammatica, i.; arte militar, i., ii.; geografia, i.–iii.; fabricas, i., ii., plates, vol. i. A French edition was printed at Padua, with the plates, says Peignot, very carefully engraved. Probably no more unmanageable body of dictionaries has ever been published except Migne's *Encyclopédie Théologique*, Paris, 1844–75, 4to, 168 vols., 101 dictionaries, 119,059 pages.

No encyclopædia has been more useful and successful, or more frequently copied, imitated, and translated, than that known as the *Conversations Lexicon* of Brockhaus. It was begun as *Conversations Lexicon mit vorzüglicher Rücksicht auf die gegenwärigen Zeiten*, Leipzic, 1796 to 1808, 8vo, 6 vols., 2762 pages, by Dr. Gotthelf Renatus Löbel (born 1st April, 1767, at Thalwitz near Wurzen in Saxony, died 14th February, 1799), who intended to supersede Hübner, and included geography, history, and in part biography, besides mythology, philosophy, natural history, etc. Vols. i.–iv. (A to R) appeared 1796 to 1800, vol. v. in 1806. Friedrich Arnold Brockhaus (born at Dortmund 4th May, 1772, settled at Amsterdam in 1801–2, where he opened a German bookseller's shop, 15th October, 1805, as Rehloff & Co., Dutch law not allowing him to use his own name) bought the work with its copyright 25th October, 1808, for 1800 thalers from the printer, who seems to have got it in payment of his bill. The editor, Christian Wilhelm Franke, by contract dated 16th November, was to finish vol. vi. by December 5, and the already projected supplement, 2 vols., by Michaelmas, 1809, for 8 thalers a printed sheet. No penalty was specified, but, says his grandson, Brockhaus was to learn that such contracts, whether under penalty or not, are not kept, for the supplement was finished only in 1811. Brockhaus issued a new impression as *Conversations Lexicon oder kurzgefasstes Handwörterbuch*, etc., 1809–11, and on removing to Altenburg in 1811 began himself to edit the 2d edition (1812–19, 10 vols.), and, when vol. iv. was published, the 3d (1814–19). He carried on both editions together until 1817, when he removed to Leipsic, and began the 4th edition as *Allgemeine Deutsche Real Encyclopädie für die gebildeten Stände. Conversations Lexikon.* This double title has ever since been retained. The 5th edition was at once begun, and was finished in 18 months. Dr. Ludwig Hain assisted in editing the 4th and 5th editions until he left Leipsic in April, 1820, when Professor F. C. Hasse took his place. The 12,000 copies of the 5th edition being exhausted while vol. x. was at press, a 2d unaltered impression of 10,000 was required in 1820, and a 3d of 10,000 in 1822. The 6th edition, 10 vols., was begun in September, 1822. Brockhaus died 20th August, 1823. His two eldest sons, Friedrich and Heinrich, who carried on the business for the heirs and became sole possessors in 1829, finished the edition with Hasse's assistance in September, 1823. The 7th edition (1827–29, 12 vols., 10,489 pages, 13,000 copies, 2d impression 14,000) was edited by Hasse. The 8th edition (1833–36, 12 vols., 10,689 pages, 31,000 copies to 1842) begun in the autumn of 1832, ended May, 1837, was edited by Dr. Karl August Espe (born February, 1804, died in the Irrenanstalt at Stötteritz near Leipsic, 24th November, 1850) with the aid of many learned and distinguished writers. A general index, Universal Register, 242 pages, was added in 1839. The 9th edition (1843–47, 15 vols., 11,470 pages, over 30,000 copies) was edited by Dr. Espe. The 10th edition (1851–55, 12,564 pages) was also in 15 vols., for convenience in reference, and was edited by Dr. August Kurtzel aided by Oskar Pilz. Friedrich Brockhaus had retired in 1849, and Dr. Heinrich Edward, elder son of Heinrich, made partner in 1854, assisted in this edition from the beginning, and Heinrich Rudolf, the younger son, partner since 1863, in the 11th (1864–68, 15 vols. of 60 sheets, 13,366 pages). Kurtzel died 24th April, 1871, and Pilz was sole editor until March, 1872, when Dr. Gustav Stockmann joined, who was alone from April until joined by Dr. Karl Wippermann in October. Besides the Universal Register of 136 pages and about 50,000 articles, each volume has an index. The supplement, 2 vols., 1764 pages, was begun in February, 1871, and finished in April, 1873. The 12th edition, begun in 1875, is to be in 15 vols. of 64 sheets, 15,300 pages, to be finished in 1880. The *Conversations Lexikon* is intended, not for scientific use, but to promote general mental improvement by giving the results of research and discovery in a simple and popular form without extended details. The articles, often too brief, are very excellent and trustworthy, especially on German subjects, give references to the best books, and include biographies of living men.

The most copious German encyclopædia is Ersch and Gruber's *Allgemeine Encyclopädie der Wissenschaften und Künste*, Leipzig, 1818–75, 151 vols., 69,893 pages, and about 360 plates, being perhaps three-fifths of the work. It was designed and begun in 1813 by Professor Johann Samuel Ersch (born at Gross Glogau, 23d June, 1766, chief librarian at Halle, died 16th January, 1828), to satisfy the wants of Germans, only in part supplied by foreign works. It was stopped by the war until 1816, when Professor Hufeland (born at Dantzic 19th October, 1760) joined, but died 25th November, 1817, while the specimen part was at press. The work is in three sections:—(1), A to G, 95 vols. 1818–75, 44,379 pages (A to Guano), edited to vol. xvii., 1828 (Chioc-Boya to Claytonia), by Ersch, who carried on nearly all the correspondence, and to vol. liv. (Gargano to Gauhe), by Professor J. G. Gruber, who joined on Hufeland's death, and was succeeded in 1851 by M. H. E. Meier, and since 1856 to vol. lxii. (Gerson to Geschlecht) by Hermann Brockhaus (third son of Friedrich Arnold, born at Amsterdam 28th Jan., 1806, professor of Sanskrit at Leipsic); (2) H to N, 31 vols., 1827–55, 14,447 pages (H to Izzo), begun by W. Müller, librarian at Dessau, who died in September, 1827, and was succeeded by Professor A. G. Hoffmann of Jena; (3) O to Z, 25 vols., 11,067 pages (O to Phyxios), edited by Meier. All articles bear the authors' names, those not ready in time were placed at the end of their letter. The longest is Griechenland, vols. 80–87, 3668 pages, with a table of contents. It began to appear after vol. 73 (Götze to Gondouin), and hence does not come in its proper place, which is in vol. 91. Gross Britannien contains 700 pages, and Indien by Benfey 356. As may be expected in a work designed by a bibliographer so renowned and industrious as Ersch, the titles of books and lists of authorities and references are very full and accurate. Among the contributors are the most learned Germans of the last 60 years. It contains much original research, and many of its articles rank among the best authorities on their respective subjects.

The *Encyclopædia Metropolitana* (London, 1845, 4to, 28 vols., issued in 59 parts in 1817–45, 22,426 pages, 565 plates) professed to give sciences and systematic arts entire and in their natural sequence, as shown in the introductory treatise on method by S. T. Coleridge. "The plan was the proposal of the poet Coleridge, and it had at least enough of a poetical character to be eminently unpractical" (*Quarterly Review,* cxiii., 379). However defective the plan, the excellence of many of the treatises by Archbishop Whately, Sir John Herschel, Professors Barlow, Peacock, De Morgan, etc., is undoubted. It is in four divisions, the last only being alphabetical:—I. *Pure Sciences,* 2 vols., 1813 pages, 16 plates, 28 treatises, include grammar, law, and theology; II. *Mixed and Applied Sciences,* 8 vols., 5391 pages, 437 plates, 42 treatises, including fine arts, useful arts, natural history and its "application," the medical sciences; III. *History and Biography,* 5 vols., 4458 pages, 7 maps, containing biography (135 essays) chronologically arranged (to Thomas Aquinas in vol. 3), and interspersed with (210) chapters on history (to 1815), as the most philosophical, interesting, and natural form (but modern lives were so many that the plan broke down, and a division of biography, to be in 2 vols., was announced but not published); IV. *Miscellaneous,* 12 vols., 10,338 pages, 105 plates, including geography, a dictionary of English (the first form of Richardson's), and descriptive natural history. It is not easy to see why geography and natural history, so essentially systematic, were thus treated, or why annuities, brewing, bridges, etc., are less systematic than sculpture, agriculture, and carpentry. The index, 364 pages, contains about 9000 articles. A re-issue in 38 vols. 4to was announced in 1849. Of a second edition, 42 vols. 8vo, 14,744 pages, belonging to divisions i. to iii., were published in 1849–58.

The very excellent and useful *English Cyclopædia* (London, 1854–62, 4to, 23 vols., 12,117 pages; supplements, 1869–73, 4 vols., 2858 pages), conducted by Charles Knight, based on the *Penny Cyclopædia* (London, 1833–46, 4to, 29 vols., 15,625 pages), of which he had the copyright, is in four divisions all alphabetical, and evidently very unequal as classes:—1, geography; 2, natural history; 3, biography (with 703 lives of living persons); 4, arts and sciences. History is given under geography, but very slightly; the nomenclature of natural history is partly popular and partly scientific; and the work contains much valuable matter, but also much that is undigested and imperfectly edited. The synoptical index, 168 pages, has four columns on a page, one for each division, so that the order is alphabetical, and yet the words are classed.

Chambers's Encyclopædia (Edinburgh, W. and R. Chambers), 1860–68, 8vo, 10 vols., 8283 pages, edited in part by the publishers, but under the charge of Dr. Andrew Findlater, as "acting editor" throughout, was founded on the 10th edition of Brockhaus. A revised edition appeared in 1874, 8320 pages. In the list of 126 contributors are J. H. Burton, Emmanuel Deutsch, Prof. Goldstücker, etc. The index of matters not having special articles contains about 1500 headings. The articles are generally excellent, more especially on Jewish literature, folk-lore, and practical science; but as in Brockhaus the scope of the work does not allow extended treatment.

The New American Cyclopædia, New York (Appleton & Co.), 1858–63, 16 vols., 12,752 pages, is the work of the editors, George Ripley and Charles Anderson Dana, and 364 contributors, chiefly American. A supplementary work, *The American Annual Cyclopædia,* a yearly 8vo vol. of about 800 pages and 250 articles, has been published since 1861. In a new edition, *The American Cyclopædia,* 1873–76, 8vo, 16 vols., 13,484 pages, by the same editors, 4 associate editors, 31 revisers, and a librarian, each article passed through the hands of 6 or 8 revisers. It is, for its extent, one of the very best encyclopædias, particularly on American subjects. (P. A. L.)

ENDIVE, *Chichorium Endivia,* L., an annual esculent plant of the natural order *Compositæ,* commonly reputed to have been introduced into Europe from the East Indies, but, according to some authorities, more probably indigenous to Egypt. There are numerous varieties of the endive, forming two groups, namely, the curled or narrow-leaved (*C. E. crispa*), and the Batavian or broad-leaved (*C. E. latifolia*), the leaves of which are not curled. The former varieties are those most used for salads, the latter being grown chiefly for culinary purposes. The plant requires a light, rich, and dry soil, in an unshaded situation. In the climate of England, sowing for the main crop should commence about the second or third week in June; but for plants required to be used young it may be as early as the latter half of April, and for winter crops up to the middle of August. The seed should be finely spread in drills 4 inches asunder, and then lightly covered. After reaching an inch in height, the young plants are thinned; and when about a month old they may be placed out at distances of 12 or 15 inches, in drills 3 inches in depth, care being taken in removing them from the seed-bed to disturb their roots as little as possible. The Batavian require more room than the curled-leaved varieties. Transplantation, where early crops are required, has been found inadvisable. Rapidity of growth is promoted by the application of liquid manures. The bleaching of endive, in order to prevent the development of the natural bitter taste of the leaves, and to improve their appearance, is begun about three months after the sowing, and is best effected either by tying the outer leaves around the inner, or, as in damp seasons, by the use of the bleaching-pot. The bleaching may be completed in ten days or so in summer, but in winter it takes three or four weeks. For late crops, protection from frost is requisite; and to secure fine winter endive, it has been recommended to take up the full-grown plants in November, and to place them under shelter, in a soil of moderately dry sand or of half-decayed peat earth. Where forcing-houses are employed, endive may be sown in January, so as to procure by the end of the following month plants ready for use.

ENDOR, an ancient town of Palestine, originally belonging to the Philistines, and chiefly memorable as the abode of the sorceress whom Saul consulted on the eve of the battle of Gilboa, in which he perished. Although situated in the territory of the tribe of Issachar, it was assigned to Manasseh. In the time of Eusebius and Jerome it still existed as a large village 4 miles south of mount Tabor; and at the same distance, on the northern slope of the lower ridge of Hermon, there is still a village of this name.

ENDOWED SCHOOLS ACTS. Since the beginning of the present reign a number of statutes have been passed dealing with the endowed grammar schools of England. The Act 3 and 4 Vict. c. 77, which notices in the preamble the great number of grammar schools in England, both of royal and private foundation, and remarks that the term "grammar" had been construed to mean Greek and Latin, and that the governors and trustees of such schools were unable to establish any other education than that expressly provided for by the foundation, empowered courts of equity to make decrees or orders extending the systems of instruction and the right of admission to any school, and to establish schemes for the application of its revenues, having due regard to the intentions of the founder. The Act 23 Vict. c. 11 enabled and required the trustees and governors of endowed schools to make such order as, without interfering with the religious teaching of the other scholars or authorizing any new religious teaching, should admit children of other denominations than that to which the foundation belongs, except where the foundation expressly requires the children to be instructed according to the formularies of such denomination. The most important public schools—Eton, Harrow, Westminster, etc.—were expressly exempted from the operation of both of these Acts. The Act 31 and 32 Vict. c. 23 annexed certain conditions to the appointment of officers in endowed schools. The most important Act of the series was the 32 and 33 Vict. c. 56 (The Endowed Schools Act, 1869), which authorized the appointment of commissioners, with power "in such manner as may render any educational endowment most conducive to the advancement of the education of boys and girls, and either of them, to alter and add to any existing, and to make new trusts, directions, and provisions in lieu of any existing trusts, directions, and provisions which affect such endowment and the education promoted thereby." The powers of the commissioners extend to all school endowments other than those specified in section 8 of the Act, which, *inter alia,* excludes schools under the Public Schools Act, 1868, voluntary schools, schools aided by parliamentary grant, endowments not necessarily educational, etc. The 36 and 37 Vict. c. 87 continues and amends in various particulars the

Act of 1869. The 37 and 38 Vict. c. 87 transfers the powers of the Endowed Schools Commissioners to the Charity Commissioners (see CHARITIES). The Public School Act, 1868, above referred to, deals with the following schools only —Eton, Winchester, Westminster, Charterhouse, Harrow, Rugby, and Shrewsbury.

ENDYMION. In the genealogy of the Iapetids Endymion is said to be the son of Aethlius, who is the son of Zeus by Protogeneia, the daughter of Deucalion and Pyrrha. The legend of Endymion was localized in Elis, the westernmost land in the Peloponnesus, where his tomb was shown in the days of Pausanias. The simplest form of the story is perhaps that of Apollodorus (i. 7, 5), who merely says that Selene (the moon) loved him, and that Zeus left him free to choose anything that he might desire, his choice being an everlasting sleep in which he might remain youthful for ever. This is simply a reversing of the myth of Eos (the morning), who forgot to ask eternal youth for her husband Tithonus, whose decrepit form she was glad to hide in a cave. In other versions Endymion is a beautiful youth, whom Selene visits while he lies asleep in the cave of Latmus. She thus becomes the mother of his fifty daughters, who have been supposed by Preller (*Greichische Mythologie*, i. 384) to denote the fifty moons of the Olympian festal cycle, but who in their number must be compared with the fifty sons or daughters of Ægyptus, Danaus, or Priam. As the parent of these children, Selene is called Asterodia, the being whose path is among the stars. These names of themselves show that this myth was so transparent that it could never be more than thinly disguised. Endymion is, in short, as his name denotes, simply the sun setting opposite to the rising moon, the word being formed in a manner analogous to Hyperion, a name signifying the ascending or high-soaring Helios or sun. The Latmian cave is the cave of forgetfulness or sleep, into which the sun plunges beneath the sea. Hence he is naturally spoken of as the son of Aethlius (the child of Protogeneia, the early dawn), who struggles and toils through his long journey across the heaven. There is nothing in the myth which warrants the idea that Endymion is a personification of sleep. Hypnus, the true god of slumber, is a conqueror whom none can resist; Endymion is simply one who cannot shake off his own sleep, a sleep so profound that they who are vexed in heart may well envy it (Theocr., *Idyll.* iii. 49).

ENERGY may be defined as the power of doing work, or of overcoming resistance. A bent spring possesses energy, for it is capable of doing work in returning to its natural form; a charge of gunpowder possesses energy, for it is capable of doing work in exploding; a Leyden jar charged with electricity possesses energy, for it is capable of doing work in being discharged. A complete account of our knowledge of energy and its transformations would require an exhaustive treatise on every branch of physical science, for natural philosophy is simply the science of energy. There are, however, certain general principles to which energy conforms in all the varied transformations which it is capable of undergoing, and of these principles we propose to give a brief sketch.

Before we can treat energy as a physical quantity we must possess some means of measuring it. If we raise 1 ℔ of matter through a foot we do a certain amount of work against the earth's attraction. If we raise 2 ℔ through the same height we do twice this amount of work, and so on for any number of pounds, so that the work done is proportional to the mass raised, and therefore to the resistance overcome. Also, if we neglect the variation of the intensity of gravity, the work done in raising 1 ℔ through 2 feet will be double of that done in raising it 1 foot. Hence we conclude that the work done varies as the resistance overcome and the distance through which it is overcome conjointly.

Now, we may select any definite quantity of work we please as our unit, as, for example, the work done in lifting a pound a foot high from the sea-level in the latitude of London, which is the unit of work generally adopted by British engineers, and is called the "foot-pound." The most useful unit for scientific purposes is one which depends only on the fundamental units of length, mass, and time, and is hence called an absolute unit. Such a unit is independent of gravity or of any other quantity which varies with the locality. Taking the centimetre, gramme, and second as our fundamental units, the most convenient unit of force is that which, acting on a gramme for a second, produces in it a velocity of a centimetre per second; this is called a Dyne. The unit of work is that which is required to overcome a resistance of a dyne over a centimetre, and is called an Erg. In the latitude of Paris the dyne is equal to the weight of about $\frac{1}{981}$ of a gramme, and the erg is the amount of work required to raise $\frac{1}{981}$ of a gramme vertically through one centimetre. A megalerg is one million ergs.

Energy is the capacity for doing work. The unit of energy should therefore be the same as that of work, and the centimetre-gramme-second (or, as it is usually called, the C.G.S.) unit of energy is the erg.

The forms of energy which are most readily recognized are of course those in which the energy can be most readily employed in doing mechanical work, and it is manifest that masses of matter which are large enough to be seen and handled are more readily dealt with mechanically than are smaller masses. Hence when useful work can be obtained from a system by simply connecting visible portions of it by a train of mechanism, such energy is more readily recognized than is that which compels us to control the behavior of molecules before we can transform it into useful work. The former is sometimes, though very improperly, called visible energy, because its transformation is always accompanied by a visible change in the system itself.

The conception of work and of energy was originally derived from observation of purely mechanical phenomena, that is to say, phenomena in which the relative positions and motions of visible portions of matter were all that were taken into consideration. Hence it is not surprising that, in those more subtle forms in which energy cannot be so readily converted into work, it should for a long while have escaped recognition after it had become familiar to the student of dynamics.

If a pound weight be suspended by a string passing over a pulley, in descending through 10 feet it is capable of raising nearly a pound weight, attached to the other end of the string, through the same height, and thus can do nearly 10 foot-pounds of work. The smoother we make the pulley the more nearly does the amount of useful work which the weight is capable of doing approach 10 foot-pounds, and if we take into account the work done against the friction of the pulley, we may say that the work done by the descending weight is 10 foot-pounds, and hence when the weight is in its elevated position we have at disposal 10 foot-pounds more energy than when it is in the lower position. It should be noticed, however, that this energy is possessed by the system consisting of the earth and pound together, in virtue of their separation, and that neither could do work without the other to attract it. The system consisting of the earth and the pound therefore possesses an amount of energy which depends on the relative positions of its two parts, and the stresses existing between them. In most mechanical systems the stresses acting between the parts can be determined when the relative positions of all the parts are known; and the energy which a system possesses in virtue of the relative positions of its parts, or its *configuration*, is called its "Potential Energy," to distinguish it from another form of energy which we shall presently consider. The word potential does not imply that this energy is not real and exists only in potentiality; it *is* energy, and has as much claim to the title as it has in any other form in which it may appear.

It is a well-known proposition in dynamics that, if a body be projected vertically upwards in vacuo, with a velocity of v centimetres per second, it will rise to a height of $\frac{v^2}{2g}$ centimetres, where g represents the numerical value of the acceleration produced by gravity in centimetre-second units. Now, if m represent the mass of the body in grammes, its weight will be mg dynes, for it will require a force of mg dynes to produce in it the acceleration denoted by g. Hence the work done in raising the mass will be represented by $mg\frac{v^2}{2g}$, that is, $\frac{1}{2}mv^2$ ergs. But it is merely in virtue of the velocity of projection that the mass is capable of rising against the resistance of gravity, and hence we must conclude that at the instant of projection it possessed $\frac{1}{2}mv^2$ units of energy. Now, whatever be the direction in which a body is moving, a frictionless constraint, like a string attached to the body, can cause its velocity to be changed into the vertical direction without any change taking place in the magnitude of the velocity. Hence we may say that if a body of mass m be moving in any direction relative to the earth, we have at disposal, in virtue of this motion, $\frac{1}{2}mv^2$ units of *energy*, and this is converted into potential energy if the body come to rest at the highest point of its path. Like potential energy, this energy is relative and is due to the motion of the body relative to the earth, for we know nothing about absolute motion in space; and, moreover, when we have brought the body to rest relative to the earth, we shall have deprived it of all the energy which we can derive from its motion. The energy is therefore possessed in common by the system consisting of the earth and the body; and the energy which a system possesses in virtue of the relative motions of its parts is called "Kinetic Energy."

A good example of the transformation of kinetic energy into potential energy, and *vice versâ*, is seen in the pendulum. When at the limits of its swing, the pendulum is for an instant at rest, and all the energy of the oscillation is potential. When passing through its position of equilibrium, since gravity can do no more work upon it without changing its fixed point of support, all the energy of oscillation is kinetic. At intermediate positions the energy is partly kinetic and partly potential.

Kinetic energy is possessed by a system of two or more bodies in virtue of the relative motion of its parts. Since our conception of velocity is essentially relative, and we know nothing about absolute velocities in space, it is plain that any property possessed by a body in virtue of its motion can be possessed by it only in relation to those bodies with respect to which it is moving, and thus a single rigid body can never be said to possess kinetic energy in virtue of the motion of its centre of mass. If a body whose mass is m grammes be moving with a velocity of v centimetres per second relative to the earth, the kinetic energy possessed by the system is $\frac{1}{2}mv^2$ ergs if m be small relative to the earth. But if we consider two bodies each of mass m, and one of them moving with velocity v relative to the other, we can only obtain $\frac{1}{4}mv^2$ units of work from this system alone, and we ought not to say that the system considered by itself possesses more than $\frac{1}{4}mv^2$ units of energy. If we include the earth in our system the whole energy will depend on the velocities of the bodies relative to the earth, and not simply on their velocities relative to one another. Hence whenever we say that the kinetic energy of a body is $\frac{1}{2}mv^2$, we mean its kinetic energy relative to the earth, and the statement is only true when the mass of the body is very small compared with that of the earth. Any general expression for the energy of a system ought to be true whatever body in the system we consider fixed. It is manifest that the expression $\frac{1}{2}mv^2$ will not be a true representation of the kinetic energy of the earth and a cannon shot if we choose to consider the shot fixed and the earth moving towards it. In fact any general expression for the energy of a system must involve the masses of *all* the bodies concerned; but if the mass of one body be infinite compared with that of any of the others we may adopt the expression $\frac{1}{2}\Sigma(mv^2)$ for the kinetic energy, the body of infinite mass being supposed at rest.

It is only when a body possesses no motion of rotation that we may speak of its velocity as a whole. If a body be rotating about an axis, it follows from D'Alembert's principle that the work it is capable of doing while being brought to rest is the same as if each particle were perfectly free and moving with the velocity which it actually possesses. Hence if the moment of inertia of a body about its axis of rotation be represented by I, and its angular velocity by ω, the work which can be done by it if we can succeed in bringing it to rest will be $\frac{1}{2}I\omega^2$. We shall see hereafter how this energy may be transformed without the help of any external body if we suppose the rotating body indefinitely extensible in any direction at right angles to the axis of rotation, so that there is a sense in which we may speak of the kinetic energy of rotation as really belonging to the rotating body.

When the stresses acting between the parts of a system depend *only* on the relative positions of those parts, the sum of the kinetic energy and potential energy of the system is always the same, provided the system be not acted upon by anything without it. Such a system is called *conservative*, and is well illustrated by the swinging pendulum above referred to. But there are some stresses the *direction* of whose action depends on that of the relative *motion* of the visible bodies between which they appear to act, while there are others whose *magnitude* also depends on the relative velocities of the bodies. When work is done against these forces no equivalent of potential energy is produced, at least in the form in which we have been accustomed to recognize it, for if the motion of the system be reversed the forces will be also reversed and will still oppose the motion. It was long believed that work done against such forces was lost, and it was not till the present century that the energy thus transformed was traced, and the principle of conservation of energy established on a sound physical basis.

The principle of the Conservation of Energy has been stated by Professor Clerk Maxwell as follows:—

"*The total energy of any body or system of bodies is a quantity which can neither be increased nor diminished by any mutual action of those bodies, though it may be transformed into any one of the forms of which energy is susceptible.*"

Hence it follows that, if a system be unaffected by any agent external to itself, the whole amount of energy possessed by it will be constant, and independent of the mutual action of its parts. If work be done upon a system or energy communicated to it from without, the energy of the system will be increased by the equivalent of the work so done or by the energy so communicated; while if the system be allowed to do work upon external bodies or in any way to communicate energy to them, the energy of the system will be diminished by the equivalent of the work so done or energy so communicated.

In order to establish this principle it might at first sight appear necessary to make direct measurements of energy in all the forms in which it can possibly present itself. But there is one form of energy which can be readily measured, and to which all other forms can be easily reduced, viz., heat. If then we transform a quantity of energy from the form in which it is possessed by the earth and a raised weight, and which can be at once determined in foot-pounds or ergs, into heat, and measure the amount of heat so produced,—and if subsequently we allow an equal amount of energy to undergo various intermediate transformations, but to be finally reduced to heat,—and if we find that under all conditions the amount of heat is the same, and in different sets of experiments proportional only to the amount of energy with which we started, we shall be justified in asserting that no energy has been lost or gained during the transformations. It is the experimental proof of this which Joule has given us during the last thirty years, but we shall refer more at length to his work shortly.

It has been recently pointed out by Thomson and Tait (*Natural Philosophy*, arts. 262 *sqq.*) that Newton was acquainted with the principle of the conservation of energy, so far as it belongs purely to mechanics. But what became of the work done against friction and such non-conservative forces was entirely unknown to Newton, and for long after his time this work was supposed to be lost. There were, however, some, even before Newton's time, who had more than a suspicion that heat was a form of energy. Bacon expressed his conviction that heat consists of a kind of motion or "brisk agitation" of the particles of matter. In the *Novum Organum*, after giving a long list of the sources of heat, some of which may fairly be adduced in support of his opinion, he says, "From these examples, taken collectively as well as singly, the nature whose limit is heat apears to be motion." In the following quotation Bacon appears to rise to the most complete appreciation of the dynamical nature of heat, nor do the most recent advances in science enable us to go much further. "It must not be thought that heat generates motion or motion heat (though in some respects this is true), but the very essence of heat, or the substantial self of heat, is motion and nothing else." Although Bacon's essay contains much sound reasoning, and many observations and experiments are cited which afford very strong evidence in favor of the theory he maintains, yet these are interspersed with so many false analogies, and such confusion between heat and the acrid or irritant properties of bodies, that we must reserve for those who came after him the credit of having established the dynamical theory of heat upon a strictly scientific basis.

After Newton's time the first important step in the history of energy was made by Benjamin Thompson, Count Rumford, and was published in the *Phil. Trans.* for 1798. Rumford was engaged in superintending the boring of cannon in the military arsenal at Munich, and was struck by the amount of heat produced by the action of the boring bar upon the brass castings. In order to see whether the heat came out of the chips he compared the capacity for heat of the chips abraded by the boring bar with that of an equal quantity of the metal cut from the block by a fine saw, and obtained the same result in the two cases, from which he concluded that "the heat produced could not possibly have been furnished at the expense of the latent heat of the metallic chips."

Rumford then turned up a hollow cylinder which was cast in one piece with a brass six-pounder, and having reduced the connection between the cylinder and cannon to a narrow neck of metal, he caused a blunt borer to press against the hollow of the cylinder with a force equal to the weight of about 10,000 ℔, while the casting was made to rotate in a lathe. By this means the mean temperature of the brass was raised through about 70° Fahr., while the amount of metal abraded was only 837 grains. The cylinder, when it was subsequently removed from the rest of the casting, was found to weigh 113·13 ℔.

In order to be sure that the heat was not due to the action of the air upon the newly exposed metallic surface, the cylinder and the end of the boring bar were immersed in 18·77 ℔ of water contained in an oak box. The temperature of the water at the commencement of the experiment was 60° Fahr., and after two horses had turned the lathe for 2½ hours the water boiled. Taking into account the heat absorbed by the box and the metal, Rumford calculated that the heat developed was sufficient to raise 26·58 ℔ of water from the freezing to the boiling point, and in this calculation the heat lost by radiation and conduction was neglected. Since one horse was capable of doing the work required, Rumford remarked that one horse can generate heat as rapidly as nine wax candles burning in the ordinary manner.

Finally, Rumford reviewed all the sources from which the heat might have been supposed to be derived, and concluded that it was simply produced by the friction, and that the supply was inexhaustible. "It is hardly necessary to add," he remarks, "that anything which any insulated body or system of bodies can continue to furnish *without limitation* cannot possibly be a *material substance;* and it appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner that heat was excited and communicated in these experiments, except it be *motion.*"

About the same time that Rumford's experiments were published, Sir Humphry Davy showed that two pieces of ice could be melted by rubbing them together in a vacuum although everything surrounding them was at a temperature below the freezing point. He did not, however, see that since the heat could not have been supplied by the ice, for ice absorbs heat in melting, this experiment afforded conclusive proof of the dynamical nature of heat.

Though we may allow that the results obtained by Rumford and Davy demonstrate satisfactorily that heat is in some way due to motion, yet they do not tell us to what particular dynamical quantity heat corresponds. For example, does the heat generated by friction vary as the friction and the time during which it acts, or is it proportional to the friction and the distance through which the rubbing bodies are displaced,—that is, to the work done against friction,—or does it involve any other conditions? If it can be shown that, however the duration and all other conditions of the experiment may be varied, the same amount of heat can in the end be always produced when the same amount of *energy* is expended, then, and only then, can we infer that heat is a form of energy, and that the energy consumed has been really transformed into heat. This Joule has done, and his experiments conclusively prove that heat and energy are of the same nature, and that all other forms of energy with which we are acquainted can be transformed into an equivalent amount of heat; and this is the condition ultimately assumed by the energy employed in doing work against friction and similar forces, which energy was in Newton's time supposed to be lost.

DEFINITION.—*The quantity of energy which, if entirely converted into heat, is capable of raising the temperature of the unit mass of water from 0° C. to 1° C., is called the mechanical equivalent of heat.*

One of the first who took in hand the determination of the mechanical equivalent of heat was Séguin, a nephew of Montgolfier. He argued that, if heat be energy, then, when it is employed in doing work, as in a steam-engine, some of the heat must itself be consumed in the operation. Hence he inferred that the amount of heat given up to the condenser of an engine when the engine is doing work must be less than when the same amount of steam is blown through the engine without doing any work. Séguin was unable to verify this experimentally, but in 1857 Hirn succeeded, not only in showing that such a difference exists, but in measuring it, and hence determining a tolerably approximate value of the mechanical equivalent of heat.

In 1839 Séguin endeavored to determine the mechanical equivalent of heat from the loss of heat suffered by steam in expanding, *assuming* that the whole of the heat so lost was consumed in doing external work against the pressure to which the steam was exposed. This assumption, however, cannot be justified, because it neglected to take account of work which might possibly have to be done *within the steam itself* during the expansion.

In 1842, Mayer, a physician at Heilbronn, published an attempt to determine the mechanical equivalent of heat from the heat produced when air is compressed. Mayer made an assumption the converse of that of Séguin, asserting that the whole of the work done in compressing the air was converted into heat, and neglecting the possibility of heat being consumed in doing work within the air itself or being produced by the transformation of internal potential energy. Joule afterwards proved (see below) that Mayer's assumption was in accordance with fact, so that his method was a sound one as far as experiment was concerned, and it was only on account of the values of the specific heats of air at constant pressure and at constant volume employed by him being very inexact that the value of the mechanical equivalent of heat obtained by Mayer was very far from the truth.

Passing over Colding, who in 1843 presented to the Royal Society of Copenhagen a paper entitled "Theses concerning Force," which clearly stated the "principle of the perpetuity of energy," and who also performed a series of experiments for the purpose of determining the heat developed by the compression of various bodies which entitle him to be mentioned among the founders of the modern theory of energy, we come to Dr. Joule of Manchester, to whom we are indebted more than to any other for the establishment of the principle of the conservation of energy on the broad basis on which it now stands. The best known of Joule's experiments was that in which a brass paddle consisting of eight arms of complicated form arranged symmetrically round an axis was made to rotate in a cylindrical vessel of water containing four fixed vanes, which allowed the passage of the arms of the paddle but prevented the water from rotating as a whole. The paddle was driven by weights connected with it by strings which passed over friction rollers, and the temperature of the water was observed by thermometers which indicated $\frac{1}{200}$th of a degree Fahrenheit. Special experiments were made to determine the work done against resistances outside the vessel of water, which amounted to about ·006 of the whole, and corrections were made for the loss of heat by radiation, the buoyancy of the air affecting the descending weights, and the energy dissipated when the weights struck the floor with a finite velocity. From these experiments Joule obtained 772·692 foot-pounds in the latitude of Manchester as equivalent to the amount of heat required to raise 1 ℔ of water through 1° Fahr. from the freezing-point. Adopting the centigrade scale, this gives 1390·846 foot-pounds as the mechanical equivalent of heat.

With an apparatus similar to the above, but smaller, made of iron and filled with mercury, Joule obtained results varying from 772·814 foot-pounds when driving weights of about 58 ℔ were employed to 775·352 foot-pounds when the driving weights were only about 19½ ℔. By causing two conical surfaces of cast-iron immersed in mercury and contained in an iron vessel to rub against one another when pressed together by a lever, Joule obtained 776·045 foot-pounds for the mechanical equivalent of heat when the heavy weights were used, and 774·93 foot-pounds with the small driving weights. In this experiment a great noise was produced, corresponding to a loss of energy, and Joule endeavored to determine the amount of energy necessary to produce an equal amount of sound from the string of a violoncello and to apply a corresponding correction.

The close agreement between the results of these experiments, differing widely as they do in their details, at least indicates that "the amount of heat produced by friction is proportional to the work done and independent of the nature of the rubbing surfaces." Joule inferred from them that the mechanical equivalent of heat is probably about 772 foot-pounds, or, employing the centigrade scale, about 1390 foot-pounds.

Previously to determining the mechanical equivalent of heat by the most accurate experimental method at his command, Joule established a series of cases in which the production of one kind of energy was accompanied by a disappearance of some other form. In 1840 he showed that when an electric current was produced by means of a dynamo-magneto-electric machine the heat generated in the conductor, when no external work was done by the current, was the same as if the energy employed in producing the current had been converted into heat by friction, thus showing that electric currents conform to the principle of the conservation of energy, since energy can neither be created nor destroyed by them. He also determined a roughly approximate value for the mechanical equivalent of heat from the results of these experiments. Extending his investigations to the currents produced by batteries, he found that the total voltaic heat generated in any circuit was proportional to the number of electro-chemical equivalents electrolyzed in each cell multiplied by the electromotive force of the battery. Now, we know that the number of electro-chemical equivalents electrolyzed is proportional to the whole amount of electricity which passed through the circuit, and the product of this by the electromotive force of the battery is the work done by the latter, so that in this case also Joule showed that the heat generated was proportional to the work done.

During his experiments on the heat produced by electric currents, Joule showed that, when a platinum wire was heated by the current so as to emit light, the heat generated in the circuit for the same amount of work done by the battery was less than when the wire was kept cold, proving that when light is produced an equivalent amount of some other form of energy must disappear.

In 1844 and 1845 Joule published a series of researches on the compression and expansion of air. A metal vessel was placed in a calorimeter and air forced into it, the amount of energy expended in compressing the air being measured. Assuming that the whole of the energy was converted into heat, when the air was subjected to a pressure of 21·5 atmospheres Joule obtained for the mechanical equivalent of heat about 824·8 foot-pounds, and when a pressure of only 10·5 atmospheres was employed the result was 796·9 foot-pounds.

In the next experiment the air was compressed as before, and then allowed to escape through a long lead tube immersed in the water of a calorimeter, and finally collected in a bell jar. The amount of heat absorbed by the air could thus be measured, while the work done by it in expanding could be readily calculated. In allowing the air to expand from a pressure of 21 atmospheres to that of 1 atmosphere the value of the mechanical equivalent of heat obtained was 821·89 foot-pounds. Between 10 atmospheres and 1 it was 815·875 foot-pounds, and between 23 and 14 atmospheres 761·74 foot-pounds.

But, unlike Mayer and Séguin, Joule was not content with assuming that when air is compressed or allowed to expand the heat generated or absorbed is the equivalent of the work done and of that only, no change being made in the internal energy of the air itself when the temperature is kept constant. To test this two vessels similar to that used in the last experiment were placed in the same calorimeter and connected by a tube with a stop-cock. One contained air at a pressure of 22 atmospheres, while the other was exhausted. On opening the stop-cock no work was done by the expanding air against external forces, since it expanded into a vacuum, and it was found that no heat was generated or absorbed. This showed that Mayer's assumption was true. On repeating the experiment when the two vessels were placed in different calorimeters, it was found that heat was absorbed by the vessel containing the compressed air, while an equal quantity of heat was produced in the calorimeter containing the exhausted vessel. The heat absorbed was consumed in giving motion to the issuing stream of air, and was reproduced by the impact of the particles on the sides of the exhausted vessel.[1]

The more recent researches of Dr. Joule and Sir William Thomson (*Phil. Trans.*, 1853, p. 357, 1854, p. 321, and 1862, p. 579) have shown that the statement that no *internal work* is done when a gas expands or contracts is not quite true, but the amount is very small in the cases of those gases which, like oxygen, hydrogen, and nitrogen, can only be liquefied by intense cold and pressure. It is worthy of note that mixtures of nitrogen and oxygen behaved more like theoretically perfect gases than either of the gases alone.

For the other contributions of Joule to our knowledge of energy, and for those of Sadi Carnot, Rankine, Clausius, Helmholtz, Sir William Thomson, James Thomson, Favre, and others, we must refer the reader to the articles on the several branches of physics, especially to HEAT.

Though we can convert the whole of the energy possessed by any mechanical system into heat, it is not in our power to perform the inverse operation, and to utilize the whole of the heat in doing mechanical work. Thus we see that different forms of energy are not equally valuable for conversion into work. The energy of a system should be measured by the amount of work it can do under the most favorable conditions which can be imagined, though we are not necessarily capable of realizing them. The ratio of the portion of the energy of a system which can under given conditions be converted into work to the whole amount of energy present is called the *availability* of the energy. If a system be removed from all communication with anything outside of itself, the whole amount of energy possessed by it will remain the same, but will of its own accord tend to undergo such transformations as will diminish its availability; for since work is done only when energy undergoes transformation, every change which it is allowed to undergo of its own accord deprives us of one opportunity of deriving useful work, that is, of converting a portion of the energy into the particular form we desire. This principle, known as the principle of the dissipation of energy, was first pointed out by Sir William Thomson in the *Philosophical Magazine* for April, 1852, and was applied by him to some of the principal problems of cosmical physics. Though controlling all phenomena of which we have any experience, the principle of the dissipation of energy rests on a very different foundation from that of the conservation of energy; for while we can conceive of no means of circumventing the latter principle, it seems that the actions of intelligent beings are subject to the former only in consequence of the rudeness of the machinery which they have at their disposal for controlling the behavior of those portions of matter in virtue of the relative motions or positions of which the energy with which they have to deal exists. If we have a weight capable of falling through a certain distance, we can employ the system consisting of the earth and weight to do an amount of useful work which is less than the potential energy possessed by the system only in consequence of the friction of the constraints, so that the limit of availability in this case is determined only by the friction which is unavoidable. Here we have to deal with a system with which we can grapple, and whose motions can be controlled at will. If, on the other hand, we have to deal with a system of molecules of whose motions we become conscious only by indirect means, while we know absolutely nothing either of the motions or positions of any individual molecules, it is obvious that we cannot grasp single molecules and control their movements so as to derive work from the system. All we can do, then, is to place the system under certain conditions, and be content with the amount of work which it is, as it were, willing to do under those conditions. It is well known that a greater proportion of the heat possessed by a body at a high temperature can be converted into work than in the case of an equal quantity of heat possessed by a body at a low temperature, so that the availability of heat increases with the temperature.

Clerk Maxwell supposed two compartments, A and B, to be filled with gas at the same temperature, and to be separated by a partition containing a number of trap-doors, each of which could be opened or closed without any expenditure of energy. An intelligent creature, or "demon," possessed of unlimited powers of vision, is placed in charge of each door, with instructions to open the door whenever a particle in A comes towards it with more than a certain velocity V, and to keep it closed against all particles in A moving with less than this velocity, but, on the other hand, to open the door whenever a particle in B approaches it with less than a certain velocity v, which is not greater than V, and to keep it closed against all particles in B moving with a greater velocity than this. By continuing this process every unit of mass which enters B will carry with it more energy than each unit which leaves B, and hence the temperature of the gas in B will be raised and that of the gas in A lowered, while no heat is lost and no energy expended, so that by the application of intelligence alone a portion of gas of uniform pressure and temperature may be divided into two parts, in which both the temperature and the pressure are different, and from which, therefore, work can be obtained at the expense of heat. If the gas do not liquefy, there seems no limit to the extent to which this operation may be carried, by increasing V and diminishing v, except that v cannot be made less than zero, which corresponds to the whole of the energy being abstracted from the gas in A and given to that in B. This shows that the principle of the dissipation of energy has control over the actions of those agents only whose faculties are too gross to enable them to grapple with those portions of matter in virtue of the relative motions or relative positions of which the energy exists with which they are concerned.

---

[1] Joule's papers will be found scattered through the *Philosophical Magazine* from 1839 to 1864; also in the *Memoirs of the Manchester Society* (2) vii. viii. ix. and (3) i.; the *Proceedings of the Manchester Society*, 1859–60, 175; *Phil. Trans.* [1850] i. 61, [1853] 357, [1854] 321, [1859] 91, [1859] 133, [1863] 579; *Proceedings of Roy. Soc.*, vi. 307, vi. 345, viii. 41, 178, viii. 355, viii. 556, viii. 564, ix. 3, ix. 254, ix. 496, x. 502; and the *Reports of the British Association* [1859] ii. 12, and [1861] ii. 83.

In April, 1875, Lord Rayleigh published a paper in the *Philosophical Magazine* on "the work which may be gained during the mixing of gases." In the preface to the paper Lord Rayleigh says, "Whenever, then, two gases are allowed to mix without the performance of work, there is dissipation of energy, and an opportunity of doing work at the expense of low temperature heat has been for ever lost." He then shows that the amount of work obtainable is equal to that which can be done by the first gas in expanding into the space occupied by the second (supposed vacuous), together with that done by the second in expanding into the space occupied by the first. In the experiment imagined by Lord Rayleigh a porous diaphragm takes the place of the partition and trap-doors imagined by Clerk Maxwell, and the gases sort themselves on account of the difference in the velocities of mean square of molecules of the different gases. When the pressure on one side of the diaphragm is greater than that on the other, work may be done at the expense of heat in pushing the diaphragm, and the operation continued until the gases are uniformly diffused. There is this difference, however, between this experiment and Clerk Maxwell's, that when the gases have diffused the experiment cannot be repeated, and it is no more contrary to the dissipation of energy than is the fact that work may be derived at the expense of heat when a gas expands into a vacuum, for the working substance is not finally restored to its original condition; while Clerk Maxwell's experiment may be supposed to be continued and work obtained till the whole of the gas has been reduced to the absolute zero of temperature, and the experiment may be repeated by again heating the gas. Independently of Lord Rayleigh, Mr. S. Tolver Preston, in November, 1877, called attention to the work which may be done at the expense of heat during the diffusion of gases, and the bearing of this upon the dissipation of energy (see *Nature*, Nov. 8, 1877).

In these experiments the molecular energy of a gas is converted into work only in virtue of the molecules being separated into classes in which their velocities are different, and these classes then allowed to act upon one another through the intervention of a suitable heat engine. If we could carry out this subdivision into classes as far as we pleased we might transform the whole of the heat of a body into work. The availability of heat is limited only by our power of bringing those particles whose motions constitute heat in bodies to rest relatively to one another; and we have precisely similar limits to the availability of the energy due to the motion of visible and tangible bodies.

If a battery of electro-motive force E maintain a current C in a conductor, and no other electro-motive force exist in the circuit, the whole of the work done will be converted into heat, and the amount of work done per second will be EC. If R denote the resistance of the whole circuit, $E = CR$, and the heat generated per second is C^2R. If the current drive an electro-magnetic engine, the reaction of the engine will produce an electro-motive force opposing the current. Suppose the current to be thus reduced to C'. Then the work done by the battery per second will be EC' or $CC'R$, while the heat generated per second will be C'^2R, so that we have the difference $(C - C')C'R$ for the energy consumed in driving the engine. The ratio of this to the whole work done by the battery is $\frac{C-C'}{C}$, so that the efficiency is increased by diminishing C'. If we could drive the engine so fast as to reduce C' to zero, the whole of the energy of the battery would be available, no heat being produced in the wires, but the horse-power of the engine would be indefinitely small. The reason why the whole of the energy of the current is not available is that heat must always be generated in a wire in which a finite current is flowing, so that, in the case of a battery in which the whole of the energy of chemical affinity is employed in producing a current, the availability of the energy is limited only on account of the resistance of the conductors, and may be increased by diminishing this resistance. The availability of the energy of electrical separation in a charged Leyden jar is also limited only by the resistance of conductors, in virtue of which an amount of heat is necessarily produced, which is greater the less the time occupied in discharging the jar. The availability of the energy of magnetization is limited by the coercive force of the magnetized material, in virtue of which any change in the intensity of magnetization is accompanied by the production of heat.

Since the motion of the centre of mass of a system is unaffected by any actions taking place between the parts of the system, it is plain that a system considered by itself cannot be said to possess energy in virtue of the motion of its centre of mass, and in estimating the energy of the system at any instant we may therefore treat this point as fixed, and consider only motions relative to it. Thus any motion of rotation we may consider to take place about an axis through the centre of mass. Now, if a system be not acted upon by any forces from without which have a moment about this axis, the product of the angular velocity of the system and of its moment of inertia about the axis of rotation will remain unchanged. Hence if we increase the moment of inertia we shall diminish the angular velocity in the inverse ratio, and therefore diminish the energy of rotation in this ratio, since the latter is proportional to the moment of inertia and the square of the angular velocity. If, then, we have a material system moving in the most general manner possible, we shall reduce its kinetic energy to a minimum by causing such actions to take place between the parts of the system as will make its moment of inertia about the invariable line as great as possible, and then changing the relative motions of the parts in such a manner that they move as if they were rigidly connected with one another. The motion of the system will then be a simple rotation with its kinetic energy as small as possible, and the greatest amount of energy will thus have been transformed.

In all the cases we have examined there is a general tendency for other forms of energy to be transformed into heat on account of the friction of rough surfaces, the resistance of conductors, or similar causes, and thus to lose availability. In some cases, as when heat is converted into the kinetic energy of moving machinery or the potential energy of raised weights, there seems to be an ascent of energy from the less available form of heat to the more available form of mechanical energy, but when this takes place there is always, accompanying it, a quantity of heat which passes from a body at a high temperature to one at a lower temperature, thus losing availability, so that on the whole there is a degradation of energy. Thus Thomson's second law of thermo-dynamics, which states that "it is impossible by means of inanimate material agency to obtain work by cooling matter below the temperature of the coldest body in the neighborhood," appears to be generally true, except when this work is obtained at the expense of some other condition of advantage, as, for example, that possessed by air at a higher pressure than the surrounding atmosphere, or by different kinds of matter which are separate and tend to diffuse, and then the work having once been obtained, the system cannot be restored to its original condition without the degradation of energy from some other source, even though the heat converted into work be restored to the working bodies.

It is sometimes important to consider the rate at which energy may be transformed into useful work, or the horse-power of the agent. It generally happens that to obtain the greatest possible amount of work from a given supply of energy, and to obtain it at the greatest rate, are conflicting interests. We have seen that the *efficiency* of an electro-magnetic engine is greatest when the current is indefinitely small, and then the rate at which it works is also indefinitely small. Jacobi showed that for a given electro-motive force in the battery the horse-power is greatest when the current is reduced to one-half of what it would be if the engine were at rest. A similar condition obtains in the steam engine, in which a great rate of working necessitates the dissipation of a large amount of energy through the resistance of the steam pipes, etc. The only way to secure a high degree of efficiency with a great horse-power in the case of the steam-engine is by increasing the section of the steam pipes and the areas of the steam ports. The efficiency of an electro-magnetic engine cannot be greater than one-half when it is working at its maximum horse-power, but we may obtain any fixed rate of working we please with a given degree of efficiency by diminishing the resistance of the battery and conductors until the maximum horse-power of the engine exceeds that at which it is to be worked by a sufficient amount. (W. G.)

ENFANTIN, Barthélemy Prosper [Le Père Enfantin], (1796–1864), one of the founders of Saint-Simonism, was born at Paris, February 8, 1796. He was the son of a banker of Dauphiny, and after receiving his early education at a lyceum, was sent in 1813 to the École Polytechnique. In March, 1814, he was one of the band of students who, on the heights of Montmartre and Saint-Chaumont, attempted resistance to the armies of the allies then engaged in the investment of Paris. In consequence of this outbreak of patriotic enthusiasm, the school was soon after closed by Louis XVIII., and the young student was compelled to seek some other career instead of that of the soldier. He first engaged himself to a country wine-merchant, for whom he travelled in Germany, Russia, and the Netherlands. In 1821 he entered a banking-house newly established at St. Petersburg, but returned two years later to Paris, where he was appointed cashier to the Caisse Hypothécaire. At the same time he became a member of the secret society of the Carbonari. In 1825 a new turn was given to his thoughts and his life by the friendship which he formed with Olinde Rodriguez, the favored disciple of Saint-Simon. Introduced by Rodriguez to the master, who was then near his end, he ardently embraced his doctrines and schemes of social, political, and religious reformation. With Rodriguez he received the last instructions of Saint-Simon, and the two were entrusted with the propagation and development of his system. Their first step was the establishment of a journal, entitled *Le Producteur*, and of a limited liability company for its support. This journal had for its motto "The Golden Age, hitherto placed by blind tradition in the past, is before us." Enfantin contributed largely to its pages; and setting forth in it not only the doctrines of his master, but also new views of his own, he gave offence to some of his supporters, and in the course of 1826 the journal was discontinued. He had now become known, and had found influential adherents in some members of the Liberal party, among them Blanqui, Bazard, Duveyrier, Pereire, Auguste Comte, Michel Chevalier, and Pierre Leroux. Before the close of 1828 they had their public meetings and lectures, not in Paris alone, but also in many provincial towns. The revolution of July (1830) brought a new freedom to the socialist reformers, and they did not fail to avail themselves of the occasion. A proclamation was issued demanding the community of goods, the abolition of the right of inheritance, and the enfranchisement of women. Enfantin now resigned his office of cashier, and devoted himself wholly to his cause. He obtained the support of the *Globe* newspaper, made appeals to the people by systematic preaching, and organized centres of action in some of the principal cities of France. The headquarters in Paris were removed from the modest rooms in the Rue Taranne, and established in large halls near the Boulevard Italien. Bazard and Enfantin were proclaimed "Pères Suprêmes." This union of the supreme fathers, however, was only nominal. A divergence was already manifest, which rapidly increased to serious difference and dissension. Bazard had devoted himself to political reform, Enfantin to social and moral change; Bazard was organizer and governor, Enfantin was teacher and consoler; the former attracted reverence, the latter love. A hopeless antagonism arose between them in reference to the proposal of Enfantin to supersede the formula of Saint-Simon, which was in substance "the greatest good of the greatest number," by another thus worded—"To each one according to his capacity, to each capacity according to its works." The breach was widened by Enfantin's announcement of his theory of the relation of man and woman, which would substitute for the "tyranny of marriage" a system of "free love." Bazard now separated from his colleague, and in his withdrawal was followed by all those whose chief aim was philosophical and political. Enfantin thus became sole "father," and the few who were chiefly attracted by his religious pretensions and aims still adhered to him. New converts joined them, and Enfantin assumed that his followers in France numbered 40,000. He wore on his breast a badge with his title of "Père," was spoken of by his preachers as "the living law," declared, and probably believed himself to be the chosen of God, and sent out emissaries in quest of a woman predestined to be the "female Messiah" and the mother of a new Saviour. The quest was very costly and altogether fruitless. No such woman was discoverable. Meanwhile believers in Enfantin and his new religion were multiplying in all parts of Europe. His extravagances and success at length brought down upon him the hand of the law. Public morality was in peril, and in May, 1832, the halls of the new sect were closed by the Government, and the father, with some of his followers, appeared before the tribunals. He now retired to his estate at Menilmontant, near Paris, where with forty disciples he continued to carry out his views. In August of the same year he was again arrested, and on his appearance in court he desired his defence to be undertaken by two women who were with him, alleging that the matter was of special concern to women. This was of course refused. The trial occupied two days, and resulted in a verdict of guilty and a sentence of imprisonment for a year with a small fine. This prosecution was the death-blow to the new society, which soon became extinct. Enfantin was released in a few months, and then, accompanied by some of his followers, he went to Egypt. He stayed there two years, and might have entered the service of the viceroy if he would have professed himself, as a few of his friends did, a Mahometan. On his return to France, a sadder and practically a wiser man, he settled down to very prosaic work. He became first a postmaster near Lyons, and in 1841 was appointed, through the influence of some of his friends who had risen to posts of power, member of a scientific commission on Algeria, which led him to engage in researches concerning North Africa and colonization in general. In 1845 he was appointed director of the Paris and Lyons railway. Three years later he established, in conjunction with Duveyrier, a daily journal, entitled *Le Crédit*, which was discontinued in 1850. He was afterwards attached to the administration of the railway from Lyons to the Mediterranean. Father Enfantin held fast by his ideal to the end, but he had renounced the hope of giving it a local habitation and a name in the degenerate obstinate world. His personal influence over those who associated with him was immense. "He was a man of a noble presence, with finely formed and expressive features. He was gentle and insinuating in manner, and possessed a calm, graceful, and winning delivery" (*Gent. Mag.*, Jan., 1865). His evident sincerity, his genuine enthusiasm, gave him his marvellous ascendency. Not a few of his disciples have since ranked amongst the most distinguished men of France. He died suddenly at Paris, September 1, 1864.

Amongst his works are—*Doctrine de Saint-Simon* (written in conjunction with several of his followers), published in 1830, and several times republished; *Économie politique et Politique* (1831); *Correspondance politique* (1835–1840); *Correspondance philosophique et religieuse* (1843–1845); and *La Vie éternelle passée, présente, future* (1861). A large number of articles by his hand appeared in *Le Producteur, L'Organisateur*,, *Le Globe*, and other periodicals. He also wrote in 1832 *Le Livre Nouveau*, intended as a substitute for the Christian Scriptures, but it was not published.

ENFIELD, a market town of Middlesex, is situated ten miles N.E. of London. A large number of its inhabitants are employed in the royal small-arms factory at Enfield Lock, where the rifle now manufactured, however, is not the "Enfield," but the Martini-Henry. Enfield has the remains of an ancient royal palace, in which Edward VI. kept his court, and where Elizabeth rested on her way to London in order to assume the crown. Near to it is Enfield Chase, disforested in 1799 and divided between various parishes and the Crown, and now occupied by several country seats of the more opulent traders of London. The population of Enfield in 1871 was 16,054.

ENFIELD, a town of the United States, in Hartford co., Connecticut, is situated on the Connecticut river, and on the railway from Hartford to Springfield, 14 miles N. of Hartford. It is connected by a bridge with Suffolk, and two miles further down the river there is a bridge by which the railroad crosses to Windsor-Locks. Enfield has a large carpet factory and extensive powder mills. It contains a community of Shakers, who are noted for their stock-raising and their culture of seeds. The population in 1870 was 6322.

ENFIELD, William (1741–1797), a dissenting divine, noted for the number and variety of his literary works, was born at Sudbury in 1741. He received his education at the dissenting academy at Daventry, under the care of Dr. Ashworth, where he passed through the usual curriculum of five years. Immediately afterwards he was chosen minister of the congregation of Benn's Garden, Liverpool, in 1763. During his residence in Liverpool he published two volumes of sermons (1768–1770), as well as a collection of hymns and family prayers, which met with a very favorable reception. In 1770 he was appointed tutor and lecturer on the belles-lettres at Warrington academy, an office which he held till the dissolution of the academy in 1783. On accepting it he obtained the degree of Doctor of Laws from the university of Edinburgh. Simultaneously with his tutorial appointment he held the pastoral charge of the dissenting congregation of Warrington. After an interval of two years spent in private tuition, he was chosen pastor of the dissenting (Unitarian) congregation of Octagon Street, Norwich, where he remained till his death, which took place November 3, 1797, in the 57th year of his age. Of the works of Dr. Enfield a considerable number are mere compilations, in which no higher quality is displayed than the taste which dictated the selection. To this class belong the *Preacher's Directory* (1771), the *English Preacher* (1773–4), the *Speaker* (1775), and others. The last named work, an elocutionary manual, has passed through numerous editions, and Enfield's name is better known in connection with it than through any of his other works. Among his original works, however, and especially those published or written at the close of his life, there are some that display considerable powers of thought and great elegance of expression. His posthumous sermons on the principal characters of the Old and New Testaments not only evince the author's ability as a commentator, but show profound insight into the ethics of history. In theology he was a Socinian. At the recommendation of Dr. Bagot, bishop of Norwich, he published an abridgment of Brucker's *History of Philosophy*, in 2 vols. 4to. He also wrote a work, entitled the *Institutes of Natural Philosophy, Theoretical and Experimental*, 4to, 1783, besides a variety of occasional pamphlets and sermons. His last literary employment was in writing for his friend Dr. John Aikin's *Biographical Dictionary*. More than half the lives in the first volume of that work are from his pen.

ENGADINE (the ancient *Vallis Eniatina* or *Œnigadena*. German *Engadin*, Italian *Engadina*), the valley of the Inn from its source to the Austrian frontier at Martinsbruck, a distance (by road) of about 65 miles. It is divided politically into two districts, the Upper and Lower Engadine, and four circles, which form part of the Gotteshausbund, one of the three leagues comprised in canton Graubünden.

The Upper Engadine has only one circle, whose chief village is Samaden. It consists of the valley of the Inn with its tributaries. The river flows through a long and straight trough, about 30 miles in length, and varying from a mile to half a mile in breadth, lying between lofty mountains, at a mean height of 5500 feet above the sea, being, after the Avers and Spöl valleys, the highest inhabited region of central Europe. Unlike most Alpine valleys the Engadine is closed at its head only by a low bank. The Maloya Pass (5942 feet) is hardly 100 feet above the lake of Sils. The lakes of Silvaplana and St. Moritz lie at nearly the same level. Samaden (ad summum Œni) stands at the junction of the Inn and its first considerable tributary the Flatzbach. This stream drains the principal glaciers of the Bernina chain, the largest glacier group in eastern Switzerland, remarkable for its closely-clustered summits, the highest of which, Piz Bernina, attains a height of 13,294 feet. Beside the Flatzbach runs the road to the Bernina Pass (7658 feet), leading into the Val Tellina. It passes Pontresina, a village of late years much frequented in summer by travellers of all nations. Its name has been assumed to be a trace of the presence of Saracens in this part of the Alps (Pons Saracenorum). Another and more plausible derivation (Pons Rhætiæ) has been suggested.

The valley below Samaden is for some distance level and uniform, and studded with flourishing hamlets. The boundary between the two Engadines lies between Scanfs and Zernetz, in an uninhabited part of the valley.

Owing to its great elevation, the scenery of the Upper Engadine has a bleak northern aspect. Pines and larches alone flourish, garden vegetables are grown only in sunny spots, and there is no tillage. The Alpine flora, however, is very rich and varied, and the Upper Engadine has been called "a paradise for the botanist." Snow always lies low on the mountain sides, and often falls even in the valley in the month of August. Hence the climate is described in the proverb—"Nine months winter and three months cold weather." The mean annual temperature is 36·5′ Fahr., that of the summer months 50·8° Fahr., of the winter 17·5° Fahr. The villages are built entirely of stone. The houses are large and roomy, a cattle stable being often included under the same roof. The small deeply-set windows bear witness to the severity of the climate. Those of the lower story are protected with iron gratings, a precaution the character of the people does not justify. An abundant use of paint and whitewash gives many of the dwellings an almost Dutch air of cleanliness, and the window-sills are usually decorated with carnations and other bright flowers.

The Lower Engadine is divided into three circles. Schuls is the chief village; next in importance is Zernetz, which stands at the junction of the Inn and Spöl. The latter stream issues from Val di Livigno, the only inhabited valley north of the Alps belonging to Italy. At this point the Inn flows for a few miles due N. through a wooded defile before resuming its N.E. course. From Suss to Finstermunz it runs in a deep channel, while the villages lie high on terraces on the mountain sides, cut off from one another by deep ravines, through which descend streams from the glaciers of the Silvretta (Silva Rhætiæ) range on the N. and from the wild dolomite ridges of the Scarlthal on the S. In the recesses of the latter bears are still found. The villages of the Lower Engadine are not so well built as those of the upper valley, and the inhabitants are said to be less energetic and more ignorant than their neighbors.

Below the village of Schuls, on the left bank of the Inn, lie the baths of Tarasp, much resorted to by North Germans. The springs to which they chiefly owe their repute are saline-akaline in character.

One of the highroads into Italy has since early times passed through the Upper Engadine. The Romans used the Bernina Pass in conjunction with the Julier. In the Middle Ages this route was the most frequented between the Mont Cenis and the Brenner, and was chosen by travellers who wished to avoid the Milanese territory and the Spanish troops. In recent years the old mule-track over the Bernina Pass has been converted into a military road, and the internal communications of the country have been opened up on all sides. Roads have been made over the Albula, Fluela, and Ofen Passes, and the villages of the Lower Engadine, previously almost inaccessible on wheels, have been united by a good road both to the upper valley and to Tyrol.

The population of the valley at the last census (1870) was 9756, of which 8402 are Protestants and 1335 Catholics. The Catholics are found chiefly at Tarasp and in the secluded glens of Samnaun and Sampnoir on the Tyrolese frontier. The people are industrious, frugal, and alive to their own interests, and at the same time more independent in manner, and less courteous to strangers, than those of central Switzerland. With the exception of Tarasp, which is mostly German, the whole district is "Romantsch." The language is a dialect known as "Ladin," nearly allied to that spoken in the Tyrolese valleys of Groden, Abtei, and Enneberg. It has a scanty literature, consisting of a translation of the Bible, some prayer and hymn books, and one newspaper, the *Fögl d'Engiadina*, printed once a week at Samaden. German is now taught in all the schools of the valley. The wealth of the inhabitants consists in their hay meadows and pastures. The lower Alps feed large herds of cows, the upper are let to Bergamasque shepherds, who travel thither every summer with their flocks. A considerable trade is also carried on in Italian products and Val Tellina wines, in which the Engadiners serve as carriers. Formerly many of them used to emigrate to different parts of the world, where they found employment, especially as pastry-cooks. Of late years the sudden influx of strangers has changed the picturesque villages into groups of hotels, and diverted the inhabitants from their former pursuits. The iron springs of St. Moritz, the cause and centre of the immigration of summer visitors from all parts of Europe, have been known since the 16th century. They had been steadily resorted to by Germans and Italians since the days of Paracelsus, though it was not till the present century that any bath-house was erected for the convenience of the guests, who found sufficient accommodation in the village. The waters are highly charged with alkaline salts and carbonate of iron, with a small proportion of phosphoric acid. and traces of iodine, bromine, etc. Their influence, in combination with mountain air, is extremely beneficial in cases requiring strong tonic treatment.

ENGEL, Johanna Jakob (1741–1802), a German writer, chiefly distinguished as a dramatist, was born at Parchim, in Mecklenburg, on the 11th September, 1741. His father was a clergyman, and he himself studied for the church, though he did not enter upon the clerical profession. He studied at Rostock and Bützow, and afterwards at Leipsic, where he took his doctor's degree in 1769. In the same year he produced his first drama, *DerDankbare Sohn*, which was received with marked approval. In 1776 he was appointed professor of moral philosophy and belles-lettres in the Joachimsthal gymnasium at Berlin, and a few years later he became tutor to the Prussian crown-prince, afterwards Frederick William III. The lessons which he gave his royal pupil in ethics and politics were published in 1798, with the title *Fürstenspiegel*, and furnish a favorable specimen of his powers as a popular philosophical writer. In 1787 he was admitted a member of the Academy of Sciences of Berlin, and in the same year he became director of the royal theatre. In the latter situation he was not successful, owing chiefly to an infirmity of temper, and he resigned it in 1794. For some time he resided at Schwerin, but on the accession of his former pupil, Frederick William III., to the throne, he was invited to return to Berlin, and received a pension. He died while on a visit to his native place on the 28th June, 1802.

Besides numerous dramas, some of which had a considerable success, Engel was the author of several valuable works on æsthetical subjects. His *Anfangsgründe einer Theorie der Dichtungsarten* (Leipsic, 1783) was one of the earliest works on the theory of poetry produced in Germany, and showed fine taste and acute critical faculty, if it lacked the loftier qualities of imagination and true poetic insight. The same excellences and the same defects were apparent in his *Ideen zu einer Mimik* (2 vols. Leipsic, 1785), written in the form of letters. His *Philosoph für die Welt* (Leipsic, 1788) consists chiefly of dialogues on men and morals, written in an attractive style, and containing much just reflection and criticism. His last work, a romance entitled *Lorenz Stark* (Leipsic, 1795), though its plot was weak, achieved a great success, in virtue of the purity of its style, the marked individuality of its characters, and the interest of its dialogues. Engel's *Sämmtliche Schriften* were published in 12 volumes at Berlin in 1801–6, and a new edition of them appeared at Frankfort in 1857.

ENGELBRECHTSDATTER, Dorthe (1634–1716), a Norwegian poetess, who enjoyed a very wide reputation throughout Scandinavia and over Germany during the first half of the 18th century. She was born at Bergen in January, 1634; her father, Engelbrecht Jörgensen, was originally rector of the high school in that city, and afterwards dean of the cathedral. In 1652 she married Ambrosius Hardenbech, a theological writer famous for his flowery funeral sermons, who succeeded her father at the cathedral, when the latter died in 1659. By the poetess Hardenbech had five sons and four daughters. In 1678 her first volume appeared, *Sjælens aandelige Sangoffer* (The Soul's Spiritual Offering of Song), published at Copenhagen. This volume of hymns and devotional pieces, very modestly brought out, had an unparalleled success, and surpassed in popularity every similar collection of that age. The fortunate poetess was invited to Denmark, and on her arrival at Copenhagen was presented at court. She was also introduced to Thomas Kingo, the father of Danish poetry, and the eminent pair greeted one another with a brace of improvised couplets, which have been preserved, and of which the poetess's reply is incomparably the neater. The next fifteen years of her life were extremely unhappy. In 1683 her husband died, and before 1698 she had buried all her nine children. In the midst of her troubles appeared her second work, the *Taareoffer* (Sacrifice of Tears), which is a continuous religious poem in four books. This was combined with the *Sangoffer*, and no less than three editions of the united works were published before her death, and many after it. In 1698 she brought out a third volume of sacred verse, *Et kristeligt Valet fra Verden* (A Christian Rejection of the World), a very tame production. In her old age she was honored by a visit from the great poet of her time, Petter Dass, who made the laborious journey to Bergen merely to see her. She died, aged eighty-two, in 1716. The first verses of Dorthe Engelbrechtsdatter are the best; her *Sangoffer* was dedicated to Jesus, the *Taareoffer* to Queen Charlotte Amalia; the change is significant of her different position in the eyes of the world. She is, all through, a dull and tiresome writer, but her immense fame among her contemporaries, and her merit as one of the earliest writers of verse in modern Norway, give her a position in literature.

ENGHIEN, Louis-Antoine-Henri de Bourbon-Condé, Duc d' (1772–1804), was the son of Henri-Louis-Joseph, prince of Condé, and of Louise-Marie-Thérèse-Bathilde d'Orléans, and was born at Chantilly on the 2d August, 1772. He was educated privately by the Abbé Millot, and was trained in the art of war by his grandfather, the prince of Condé, with whom he was present at the battle of St. Omer in 1788. In 1789, he, along with the other members of his family, went into exile. In 1792 he joined the royalist forces under his father in Flanders, and on the dissolution of this army he served under his grandfather, and specially distinguished himself at the battle of Berstheim in 1793. In 1794 he was made knight of the order of St. Louis, and from 1796 to 1799 he commanded the vanguard of his grandfather's forces. When these were disbanded in 1801, he contracted a private marriage with the princess Charlotte, niece of Cardinal de Rohan, and took up his residence near Ettenheim, in Baden. Being suspected of concocting a plot against Napoleon Bonaparte, spies were placed to watch his movements, who reported, it is said falsely, that he was in the habit of making frequent secret journeys along with General Dumouriez. Bonaparte therefore thought it necessary to seize his papers, and on the 14th March, 1804, caused his château to be surrounded by 400 gendarmes, who took the duke prisoner, and conducted him to Strasburg. After being brought to Paris on the 20th March, he was conducted to Vincennes, where he was tried by court-martial, and without being found guilty of any definite charges, was on the morning of the 21st at four o'clock condemned to death as a traitor, Half an hour afterwards he was led out to execution, and as soon as he was dead he was thrown into a grave, which, in anticipation of his sentence, had been prepared beforehand. Upon Napoleon's conduct in these arbitrary proceedings various interpretations have been put, but there are scarcely materials for forming a decisive judgment. It was in reference to the execution of the Duc d'Enghien that Fouché made the remark which has passed into a proverb: "It was worse than a crime; it was a blunder." After the Restoration the remains of the duke were removed to the chapel of the castle at Vincennes.

ENGINEERING—the art of designing and constructing works—embraces a very wide range of subjects, and the different departments into which the profession is now divided do not admit of very strict definition; but it may be mentioned that *civil engineering* includes the design and construction of canals, river navigations, harbors, docks, roads, bridges, railways, lighthouses, water supply, irrigation, sew-

erage, gas supply, telegraphs, etc.; *mechanical engineering* includes machinery, mill-work, steam-engines, iron shipbuilding, agricultural implements, etc.; *mining engineering* includes the working and raising of coal, iron, lead, copper, etc., and other minerals; and *military engineering* includes fortifications, gunnery, artillery, telegraphy, etc., as applied in warfare.

Plate I. Situation.

ENGLAND.—Part I.—Geography and Statistics.—I. *Situation.—Soil and Climate.—Political and Civil Divisions.*—England, comprising, with Wales, the southern portion of the island of Great Britain, extends from 49° 48′ to 55° 45′ N. lat., and from 1° 45′ E. to 5° 44′ W. long., and covers an area of 58,320 square miles. It corresponds in latitude with Northern Germany and the Netherlands. In shape it is nearly triangular; and owing to its being surrounded by the sea on all sides, except for a distance of about seventy miles on the Scottish border, it has a most extensive coast-line. The seas which encircle it are the German Ocean or North Sea on the E., and the Atlantic Ocean on the W. and S., the latter receiving in some of its parts the names of the Irish or St. George's Channel, and of the English Channel. The coast is much indented, more particularly on the Atlantic side, the total length, following the indentations, being estimated at over 2000 miles.

Physical structure.

There are few countries more diversified in physical structure, or in soil, climate and natural scenery, than England. As regards physical structure, it has been truly described to be in itself "an epitome of the geology of almost the whole of Europe." Nearly all the formations of the earth's crust, from the Silurian upwards to the most recent, are to be found, in layers more or less thick, in different parts of England. The lowest geological formations, known in general as Primary or Palæozoic, are met with principally in the north and north-west of England, in the counties of Cumberland and Westmoreland, and in North Wales. The rocks of Cumberland and North Wales, belonging to the Lower Silurian formation, consist mainly of slaty and gritty strata, interbedded with various kinds of felspathic lava and volcanic ashes, accompanied by numerous bosses and dykes of greenstone, quartz-porphyry, and other igneous rocks. These latter contribute greatly to give rise to that peculiar mountainous aspect which distinguishes these districts. The next geological formation above that of the Silurian is found in the Old Red Sandstone, and the so-called Devonian rocks, which occupy extensive tracts in Devonshire, Cornwall, South Wales, Herefordshire, and Worcestershire. Above these strata comes the Carboniferous Limestone, composed entirely of sea-shells, encrinites, and other organic remains, which formation, stretching from South Wales through the south-west of England into Derbyshire, attains in parts a thickness of 3000 feet and more. Next above the Carboniferous Limestone come the strata, all important to England, known as the Coal Measures, a term originally used by the miners. The beds of coal, solid basis of England's modern supremacy in arts, manufactures, and, to some extent, political power, lie upon a peculiar stratum, which generally, but not always, is of the nature of fire-clay. Coal itself is well known to consist of mineralized vegetable matter, the intermingled shales and sandstones still showing the impressions of trunks of trees, ferns, and reed-like plants, and it is supposed that this fire-clay was the original soil upon which grew the priceless treasure.

Geological changes.

The Coal Measures are covered by the Permian rocks of England, which complete the geological formation to which the name of Palæozoic or Primary strata has been given. "During the time they were forming," says Professor Ramsay, "this part of the world suffered many ups and downs, accompanied by large denudations; but at the close of the Permian period, a disturbance of the strata on the greatest scale put an end to this great Palæozoic epoch over all our area, and much more besides, and from the Permian beds downwards to the Cambrian strata a large part of what is now England was heaved up and formed dry land, to be again wasted and worn away by sea-waves and rivers, and all the common atmospheric agencies. This old land in great part consisted of what we now know as Wales, and the adjacent counties of Herefordshire, Monmouthshire, and Shropshire, of part of Devon and Cornwall, and probably the Pennine chain, and all the mountainous parts of Scotland. Around old Wales, on three sides of Cumberland, and probably all round and over great part of Devon and Cornwall, the New Red Sandstone was deposited. Part at least of this oldest of the Secondary rocks was formed of the waste of the older Palæozoic strata that had then risen above the surface of the water."

Pre-historic England.

If, in the physical structure of England, the Primary strata form a highly important element as containing the Coal Measures, the more immediate nature of the soil is determined by the Secondary and Tertiary formations. Among the Secondary strata, none are more interesting than the so-called "Wealden series" of southern England. Geologists are agreed upon the fact that the Wealden and Purbeck beds represent the delta of an immense river, equal in size to the modern Ganges or the Mississippi, the waters of which carried down to its mouth the bodies of huge reptiles and mammalia now extinct, or the semblance of which is to be found only in the tropical regions. But if this much is ascertained, by the evidence of organic remains found in abundance in Kent and Sussex, there is, and in all likelihood ever will be, complete ignorance as to the shape and extent of the continent which this great river drained, and of which England then formed a part. Professor Ramsay surmises that "in size it must have been far larger than Europe, and probably as large as Asia, or the great continents of North or South America."

Alterations of coast-line.

The formations of the Tertiary or Eocene period lie all over England, the most recent being represented by the alluvial beds of Norfolk, Suffolk, and South Hampshire, and of the basin of the Thames. The whole of the east coast of England, and a great part of the south coast, not only bear the mark of the most recent geological changes that have taken place in this country, but are affected by a continuation of them to this day. A long extent of coast-line constantly undergoes alterations, in some instances the land gaining upon the sea, and in others, rather less numerous, the sea upon the land. The whole of Romney Marsh, in Kent, embracing upwards of 24,000 acres, formerly constituted an arm of the sea, where vessels rode in deep water, carrying produce to ports which are no more in existence. Lydd, or, as it is called in old records, Hlyda, and Romney, though maritime still in name, retaining some of the ancient privileges of the Cinque Ports, have become, through changes in the coast-line, small inland towns; and the same has been the fate of Rye, Winchelsea, and other places in that district. Again, the Isle of Thanet, in the north-eastern corner of Kent, has ceased to be an island at all but in name. The wide estuary of the sea, separating it from the mainland, and through which ships in comparatively recent times sailed from the English Channel into the Thames, using it as the shortest road from the south to London, has entirely disappeared, leaving barely a rill of water to mark its former existence.

Encroachments of the sea.

If the sea retreated on some parts of the coast, it encroached, and is encroaching, on the firm land over a considerable extent of other coast-line on the German Ocean, as well as on the English Channel. Ravenspur, once an important town of Yorkshire, where Bolingbroke, afterwards Henry IV., landed in 1399, is now submerged by the sea waves; and Eccles-by-the-Sea, Cromer, and other ancient ports in Norfolk have met with the same fate. It is a common occurrence for the pedestrian who rambles over the Kentish hills bounding the narrower parts of the English Channel, to find that the path he is following suddenly comes to an end at the edge of the cliff, interrupted by a vertical precipice towards the shore. The process of destruction, slow in some places, is so rapid in others that it can be traced from month to month, and even from week to week—the incessant roll of the tides washing away the soft Eocene strata forming the base of the cliffs, and leaving the summits to roll over into the sea. It is the same in Yorkshire as in Kent. Over a distance of thirty-six miles, between Bridlington and Kilnsea, says Professor Phillips, "the materials which fall from the wasting cliff are sorted by the tide; the whole shore is in motion; every cliff is hastening to its fall; the parishes are contracted, the churches wasted away." Many cliffs of the east coast, from the Humber to the mouth of the Thames, are suffering from this destructive action of the sea, in some places at an average rate of from 4 to 5 yards a year, or a quarter of a mile in a century.

Mountains and lakes.

In conformity with the geological structure of England, its mountains lie in the north and west, falling into undulating ground in the centre and towards the south, and leaving the eastern districts, bordered by the German Ocean, a uniform plain. The mountains of England may be looked upon as one principal chain, often interrupted, however, and with endless ramifications, stretching from the Scottish border, in Northumberland, down to the western end of Cornwall, jutting out there into the Atlantic. The chain, traced in this direction, commences with the Cheviot Hills, the highest summit of which is Cheviot Peak, in Northumberland, 2676 feet above the level of the sea. Stretching south-westward, the chain next merges into the mountain ranges of Cumberland and Westmoreland, comprising Skiddaw, 3022 feet, Helvellyn, 3118 feet, and Scawfell, 3208 feet, above the level of the sea. Within these ranges lie the only notable lakes of England, the largest of which, however, Windermere, does not cover more than three square miles. After sending out numerous branches eastwards into the county of York, the chain sinks to modest elevations in Lancashire and Cheshire, but rises again in Wales, where it attains its greatest height in the summit of Wyddva, the pinnacle of the Snowdon range, 3571 feet above the sea. Partly lost in the Bristol Channel, and partly ramifying through Gloucestershire, Wilts, and Somerset, the chain next rises into high table-land in Devonshire—Dartmoor Forest, averaging an elevation of 1500 feet above the sea-level, forming its most elevated portion. The chain gradually declines from Dartmoor to the Land's End, and becomes also more contracted in that direction. From the Dunkerry Beacon, on Exmoor, 1668 feet above the sea, the mountain range goes sinking on to Carnwarth, in Cornwall, 849 feet; to Cara Brea, 697 feet; and, finally, to the famous headland of Bolerium, the granite masses of which oppose the ever-surging waters of the Atlantic, but rise only about 60 feet above them.

Rivers.

Essentially dependent on the configuration of the chain of mountains traversing England is that of its rivers. As the mountainous regions are in the west, the principal rivers flow away from them, towards the east, with but few exceptions. Surrounded by the sea, and with a moist atmosphere, England has a comparatively large number of rivers, though none of them of great length, their course being in most instances the shortest allowed by the configuration of the island. At the head of English rivers, with acknowledged supremacy over the rest, stands the Thames. It drains an area of 6160 square miles, exclusive of its lower estuary, calculated to embrace an additional drainage of about 4000 square miles. Next, in extent of area of drainage, come the Trent and Ouse, the joint waters of which form the Humber, carrying off the rainfall from 9550 square miles of land, or about one-sixth of the whole of England. The Witham, the Welland, the Nen and their tributaries, flowing into the old estuary of the Wash, drain together an area of 5850 square miles. In comparison with the drainage area of these rivers, running principally from east to west, that of currents following an opposite direction is small; but several of them are nevertheless of great commercial and industrial importance. Foremost among these westerly-flowing rivers stands the Severn, the source of which is only a short distance from that of the Thames, the watershed being formed here by the narrow Oolitic escarpment of the Cotswold hills. The Severn drains an area of 8580 square miles, being more than that of all the other westward-running rivers together. Next to it stand the Mersey, which, with its sea-estuary, drains 1750 square miles, the Avon, which drains 1210 square miles, and the Eden, which drains 995 square miles of land. In Camden's *Britannia*, published in 1605, there is a list enumerating 553 rivers and streams, with separate names, in England and Wales; but it cannot be said that there are, at the utmost, more than fifty rivers that can properly be described as navigable. The former importance of the rivers of England, connected with each other by a vast network of canals, for inland navigation, has suffered much since the introduction of railways; still they continue of great benefit for cheap, if slow, communication. Of the highest commercial value still are the Thames, the Humber, the Mersey, and the Severn, but these four principal English rivers derive their importance mainly, if not entirely, from being arms of the sea.

Climate.

Affected by its insular position, with no part of its land more than a hundred miles from the sea, and perhaps equally as much—though modern scientific investigation has not quite set this matter at rest—by that most remarkable current of the ocean known as the Gulf Stream, the climate of England is much milder than that of any other country in the same latitude on the continent of Europe or in America. The mean annual temperature of England in recent years has been 49·7°,—that of summer averaging 60·8°, and that of winter 39·5°. The principal cause of this very high as well as very equable temperature, contrasting to a marvellous extent with that of other countries in like latitude, such as, for example, Northern Canada, is generally ascribed, with but few dissenting opinions, to the constant flow of heated water bathing the western shore of the island. The vast current of the Gulf Stream, originating within the land-locked area of the Gulf of Mexico, where the tropical sun is heating the waters as in an immense caldron, after running for some distance eastward into the open ocean, then turns direct to the north-east, so that the first land it meets with, and which feels its effect, is the shores of Ireland and England. The actual amount of heat so given to England must be enormous, since the temperature of the Gulf Stream is at least 8° above that of the surrounding waters of the North Atlantic. A recent scientific traveller, making experiments in a voyage from England to the United States, found that, while in the Gulf Stream the water was at sunrise always not less than 4° above the temperature of the air, by a sudden change, on quitting the north-easterly current, the temperature of the waves was found to be, on the average, 4° below that of the air. England is thus in the position of a great hot-house, kept above the surrounding temperature by never-ending currents of warm air.

Rainfall.

But it is not warmth alone, but moisture, which the Gulf Stream gives to England. Here, as in the greater part of western Europe, the prevailing winds are from the south-west, bringing with them the warm, moist air of the great Atlantic current, and discharging it in rainfall all over the land. This is strikingly shown in the statistics of rainfall in England, which prove it far higher in the western than in the eastern counties, and greatest in those parts where the moist Atlantic air-currents are unimpeded by mountain ranges. In the extreme south-west, in Cornwall, from 22 to 47 inches of rain fall every year, and the average may be taken at 36 inches; while in the adjoining county, Devonshire, a little further inland, the average is but 32 inches. However, the high range of the Dartmoor hills causes a much greater variation in the amount of rainfall in the latter county than in the former; for while no less than 52·33 inches fall on the summit of Dartmoor, only 19·87 inches fall at Sidmouth, lying sheltered to the west. The same is the case further east, in Somersetshire, where 36·76 inches of rain fall annually at West Harptree, facing the Bristol Channel, while only 19 inches fall at Taunton, shut off from the moist gulf current by the Exmoor range. So it is everywhere all over England, with the general result that in the west, and more especially the southern parts of it, there is more rainfall than in the east, the variations also being much less in the latter districts. In Dorsetshire the annual rainfall varies from 18·45 inches at Abbotsbury to 29·05 inches at Blandford, and in Wiltshire from 18·14 inches at Chippenham to 25·20 inches at Salisbury. Further eastward, in Hampshire, the variation is from 16·51 inches at Aldershot to 26·90 inches in Woolmer Forest; while in Sussex, nearer the sea, it is from 18·18 inches at Hastings to 32·79 inches at Chichester. In the metropolitan counties of Middlesex, Kent, and Surrey the variations are no greater than from 16·22 inches at Hampstead to 28·90 inches at Cranbrook. The highest rainfall anywhere yet ascertained in England and Wales was at Beddgelert, Carnarvonshire, where it reached the enormous amount of 101·58 inches in the year 1870. Lying on the western slope of the highest summit of the Snowdon range, close to the Atlantic, the little village received a surcharge of the moist air of the Gulf Stream.

Soil and fertility.

Co-operating in their influence, climate and geological formation have given England a soil moderately fertile, yet adapted on the whole more for pasturage than for agriculture. In Wales, and other parts of northern and western England through which stretch the principal mountain ranges, the Silurian rocks, covered on their upper surface chiefly with hard gritty and slaty material, difficult to decompose by atmospheric action, form but little soil, so that the ground must to a large extent remain untilled, leaving it at the same time well adapted for pastoral purposes. Again, through the inland counties, from Northumberland to Derbyshire, there runs another long tract of hilly country, composed of carboniferous rocks, so constituted as to be unfit for ordinary agriculture, except where intersected by stream-fed valleys. Further east come the bleak moorlands of Yorkshire, which, barren in their nature, are being surrounded and intersected by some of the most fertile tracts in England, extremely well cultivated and thickly inhabited. On the whole, it may be said that while much of the high-lying ground is fit only for pastoral purposes, the low lands are more or less fertile, the extreme moisture of the air having caused the complete disintegration even of such old geological formations as those of the Red Sandstone. It is a somewhat singular fact that nearly all the districts of England, where fruit trees are grown in large quantities, lie chiefly upon red rocks, sometimes of the Old and sometimes of the New Sandstone strata. There cannot be a doubt, however, that, on the whole, the soil of England would be very barren, repaying poorly the labors of the husbandman, but for the vast cover of warmth and moisture received from the waters of the Atlantic, which favors it as the sun of more southerly regions and makes its fauna and flora equal to those of any country in the temperate zone.

Civil divisions.

The physical aspect of England has had little to do with its civil divisions, which are somewhat arbitrary, and remote in their origin. The division of the country into tythings, hundreds, and counties is generally attributed, on the authority of Ingulphus, to King Alfred, but it is more probable that he only systematized what already existed, in the general survey which was taken during his reign. English county names occur in history before the extinction of the Heptarchy, some of the smaller kingdoms of which, as Kent, Sussex, and Essex, became counties under the new political settlement. At the same time, the kingdom of Wessex was composed of counties with still existing names, Berkshire, Hampshire, Wiltshire, and Somersetshire. Under King Alfred's rearrangement, virtually that of the present day, as far as the larger divisions are concerned, physical boundaries were frequently disregarded, which had its cause probably in the existence of the older political borders, such as those existing during the Heptarchy. On the east coast of England, the divisions generally conform with the physical features: the Tyne, Tees, Humber, Wash, Yare, Stour, and Thames separate the counties of Northumberland, Durham, Yorkshire, Lincolnshire, Norfolk, Suffolk, Essex, and Kent. The same, however, is not the case on the south and southwest coast, the smaller rivers of which were disregarded in fixing the borders of Kent, Sussex, Hampshire, and Devon. Again, the east-running Thames divides counties from its mouth almost up to its source; while the westerly Severn forms not a single boundary, even for a short distance, from its spring down to its sea estuary. Finally, the dividing line between England and Scotland is mainly artificial in the west, while in the east are the natural boundaries of the Tweed and the Cheviot Hills.

Counties and hundreds.

Modern legislation has made few changes in the ancient divisions of England into counties, or shires, and hundreds. Each of the forty counties of England and twelve counties of Wales is still primarily divided into hundreds, although the borders thus formed are little more than nominal, the hundreds having become practically extinct as an administrative subdivision. Originally signifying a district containing a hundred families, the division lost its meaning entirely with the unequal increase of population, and at present, while some hundreds count their population by hundreds of thousands, others have not gone far beyond the number that gave rise to the name. At the census of 1871 the number of hundreds, or their equivalents, for which the population was separately shown was 818. In naming the subdivisions corresponding to hundreds, the ancient word "wapentake" is still adopted officially as regards the counties of York, Lincoln, and Nottingham,—Yorkshire, exclusive of the city of York, and Lincolnshire being each divided into three parts, consisting of a given number of wapentakes. In Cumberland and Westmoreland the hundreds are called "wards," while in Kent they are grouped into "lathes," and in Sussex into "rapes."

Boroughs.

Intimately connected with the division into hundreds in former times was that into boroughs. The old Saxon borough, in fact, was nothing more than a hundred, or a group of hundreds, encircled by a moat, a stockade, or a wall. All the inhabitants of the borough, or burgesses, were freemen, bound to each other as neighbors, sharing common burdens, and responsible for each other to surrounding communities. As the boroughs grew in size and importance, the hundred lost its former significance; still for a long time the original principle was kept in view of having the same subdivision, organization, and government for town and country populations. Many of the ancient boroughs have now fallen into decay, while new boroughs sprang up in many parts of the country with the rapid progress of population which commenced after the middle of the last century. In 1835 a great change was made in their constitution, and the limits of many were enlarged by the adoption of new boundaries. The change was the result of the labors of a parliamentary commission appointed "to inquire into municipal corporations."

Municipal corporations.

The parliamentary commissioners experienced, at the outset of their work, considerable difficulty in ascertaining the exact number of corporate bodies in England and Wales. Acting upon the best information they were able to collect, they visited and instituted inquiries in 285 places. It was found that 16 of them contained corporations of an exclusively manorial character; that 89 could claim to be properly boroughs; and that the remainder, 178 in number, required legislation to settle their rights and privileges. The latter, accordingly, were placed under the operation of the Municipal Corporation Act, 5 and 6 Will. IV. c. 76. Subsequently to the passing of this Act, two more old boroughs, Ashton-under-Lyne and Hartlepool, were brought under its provision by the grant of new charters.

It was provided for by section 141 of the Municipal Corporation Act that any towns, on the petition of the inhabitant householders, may have granted to them charters of incorporation if Her Majesty, by the advice of the Privy Council, shall think fit to accede to the request. The number of towns which thus obtained charters has since 1835 been 45; but the provisions of the Act were not universally adopted, and to this day a number of towns, some of considerable importance, are still without municipal organization. At the census of 1871, the total number of municipal boroughs was 224, containing more than one-fourth of the population of England and Wales.

Cinque Ports.

Claiming high rank among the municipal corporations of England, and forming one of the most ancient and celebrated subdivisions, or jurisdictions, of the country, are the Cinque Ports. The Cinque Ports existed as self-governing boroughs from a very early time, though the exact date of their incorporation is not known. It is stated in Jeake's *Charters of the Cinque Ports* that in the records of the town of Rye there is a memorandum that "the five Ports were enfranchised in the time of King Edward the Confessor." The five ports originating the title were Hastings, Romney, Hythe, Dover, and Sandwich. To these were added the so-called "ancient towns" of Rye and Winchelsea, which were placed, as regards rights and privileges, on the same footing as the original Cinque Ports. Each of the seven towns, with the exception of Winchelsea, had one or more "members," or "limbs," placed under the mantle of its privileges, very important for many centuries, one of them being an almost entire exemption from taxes levied by the king. In early times these "members" were in a great measure dependent from their respective ports, but the old connection has long ceased. Most of the old "members" are at present corporate towns, and therefore completely independent, and only the few that are not remain under the municipal jurisdiction of their parent ports. The still existing privileges of the Cinque Ports, including jurisdiction of the south coast from Seaford in Sussex to the mouth of the Thames, are of no great importance, but they are favored by a large share of parliamentary representations. (See also vol. v. p. 687.)

Parliamentary divisions.

Unlike the civil divisions of the country, those formed for parliamentary representation are mainly of recent date. Vast changes in the character of this representation—the origin of which is involved in much obscurity—were made by the Reform Bill of 1832; and others, scarcely less important, by the statute of 30 and 31 Vict. c. 102, known as the Reform Act of 1867. By the latter Act, the existing franchise was not only much enlarged, but new divisions of counties were made for electoral purposes, while the limits of many boroughs were extended, new ones created, and old ones excluded from the list. The new parliamentary boroughs created by the Act of 1867 were Burnley, Chelsea, Darlington, Dewsbury, Gravesend, Hackney, Hartlepool, Middlesborough, Staleybridge, Stockton, and Wednesbury; a representative was also given to the university of London, and additional ones to Birmingham, Leeds, Liverpool, Manchestor, Merthyr Tydfil, and Salford. On the other hand, 4 boroughs were disfranchised immediately by the Act, and 7 more in 1868, the year after its passing, while 36 were reduced to one representative instead of two. In the new division of counties made by the Reform Act of 1867, Cheshire and Lincolnshire were separated into North, Mid, and South; Devonshire and Derbyshire into North, South, and East; Essex into North-East, North-West, and South; Norfolk into West, North-East, and South-East; Somersetshire into East, Mid, and West; and the West Riding of Yorkshire into North, Mid, and South; with minor alterations. These rearrangements of parliamentary representation were more than justified by the changes of population brought about by time. Within the parliamentary boroughs the population increased 16·1 per cent. from 1851 to 1861, and 23·3 per cent. from 1861–71; while outside them the increase was only 8·9 per cent. in the first, and 5·5 per cent. in the second decennial period.

Judicial divisions.

Much less systematic than the parliamentary are the judicial divisions of the country. There is in all of them a striking want of coherence, even as regards the administration of the law. The circuits of the judges do not consist of any definite number of the county-court circuits, nor are the county-court circuits aggregates of the petty sessional divisions. For the purposes of assizes and jail delivery, there are in England eight circuits of the judges, besides the jurisdiction of the central criminal court in London. The eight circuits of the judges have received the names of the Home, Midland, Norfolk, Oxford, Northern, Western, North Wales, and South Wales circuits, indicating the counties which they embrace. Based chiefly on the old boundaries of hundreds, all the counties of England and Wales have divisions for the purposes of special and petty sessions. By the authority of various Acts of Parliament, the justices at quarter sessions are allowed to alter and rearrange these sessional divisions, making them conformable, if so inclined, to the boundaries of poor-law unions. The last census returns show that in 1871 there were 700 sessional divisions in England and Wales, besides 193 boroughs with petty sessions, 97 of the latter having also separate quarter sessions. For police purposes there were, at the same time, 622 divisions, including 167 boroughs possessing independent police control.

Ecclesiastical divisions.

Quite as early as the division of the country into hundreds was that into ecclesiastical districts. But they varied much, both in number and extent, up to the time of the Reformation, and there have been constant alterations up to the present time. The ancient division of the land for ecclesiastical purposes was exclusively into parishes, or districts containing a church; but as the population went on increasing, and additional places of worship came to be erected, some portions of the old parishes were generally assigned to the newly formed districts. First known simply as chapelries, these districts gradually acquired boundaries as definite, and as fully recognized by law, as those of the parent parish. In recent years, the term parish has acquired a rather uncertain meaning, being used in a twofold sense,—the clergy adhering to the old signification of ecclesiastical district, while the poor-law authorities make it the designation of boundaries separately rated for the relief of the poor. In the census returns for 1871, the term "civil parish" was adopted for the poor-law parish, to distinguish it from the ecclesiastical parish. The exact number of ecclesiastical parishes was not ascertained at the census of 1871, which only refers to "ecclesiastical districts," 3000 in number; and in the absence of other official information, it is difficult to calculate it, the more so as new parishes are being constantly formed by the action of the Ecclesiastical Commission, established in 1836 by Act 6 and 7 Will. c. 77. According to estimates based on the returns of the *Clergy List*, there are at present about 13,500 ecclesiastical parishes in England and Wales. They are grouped in 728 rural deaneries, with further division into 78 archdeaconries, 30 episcopal dioceses, and 2 archiepiscopal provinces.

Miscellaneous divisions.

Besides the divisions already enumerated, there are various others of minor importance, or not in frequent use. Of this character are the so-called lieutenancy subdivisions, established to carry out the laws affecting the militia. Within the boundaries thus formed, lists are kept containing the names of all men liable to serve, under certain circumstances, in the militia of England and Wales, so as to keep the force in permanency. A subdivision of another kind is that of the country into highway districts. These divisions were constituted under the Act 25 and 26 Vict. c. 61, which gave power to justices in general, or quarter sessions, to form special boundaries, consisting of parishes and places not within the jurisdiction of other boards or legal authorities, for the better management of highways. The Act came into effect in 1863, but its provisions, being optional, were not widely adopted; it led to the formation of not quite 500 highway districts. Their extent and population were not given in the census returns of 1871.

Complexity of existing divisions.

In the introduction to the report on the census of England and Wales, the registrar-general furnished a list of the various divisions of the country, showing their complexity. He classed the whole of the existing divisions, including those made for the special purpose of taking the census, into six orders, as follows:—

Order.	Subdivisions.	Number of Subdivisions.
I.	England	1
	Wales	1
II.	Registration Divisions	11
	Counties Proper	52
	Parliamentary Counties and Divisions of Counties	95
III.	Hundreds, Wapentakes, Wards, Liberties, Sokes, and Boroughs	1,042
	Petty Sessional Divisions and Boroughs	893
	Lieutenancy Subdivisions	621
	Poor Law Unions	647
	Registration Districts	626
IV.	Registration Sub-districts	2,195
V.	Parishes, Townships, or places with separate returns of population	15,416
	Enumeration Districts	32,543
VI.	Parliamentary Boroughs	198
	Municipal Boroughs	224
	Local Board Districts	721
	Towns with Improvement Commissioners	88
	Other Large Towns	96
	Highway Districts	443
	Ecclesiastical Districts	3,000

Commenting upon the extraordinary number of divisions and subdivisions of England and Wales, the registrar-general remarks that "it is a peculiarity of this country that nearly every public authority divides the country differently, and with little or no reference to other divisions; each authority appears to be unacquainted with the existence, or at least the work, of the others." He gives at the same time his opinion that "one simple connected series of subdivisions of the country" would not only simplify the census takings, greatly disturbed at present by "the multiplicity, entanglement, and want of harmony in the groups," but would still more be an aid towards reducing "the difficulties of local administration."

II. *Area and Population.—Vital Statistics.—Emigration.*

Former estimates of population.

Until the beginning of the present century, there existed no other knowledge of the actual area and population of the country but what was given in the vaguest estimates. But there can be little doubt that the population of England and Wales was almost stationary for centuries, owing chiefly to want of intercommunication, which led to famines, more or less severe—it being a common occurrence that, while one county, with a good harvest, was revelling in abundance, the people of the adjoining one were starving. It is calculated, on the basis of a number of parish registers, that in 1650 the population of England and Wales numbered 5,450,000, having probably risen less than half a million during the lapse of a century. In the course of another century, when there was a feeble commencement of road-making, the increase amounted, probably, to close upon a million, the calculated population of 1750 being 6,400,000.

From that time began a marked increase, and at the taking of the first census, in 1801, it was ascertained that the population, living on an area of 58,320 square miles, or 37,324,883 acres, numbered 8,892,536, being—if the former estimates were approximately correct—an increase of very nearly 2½ millions in little over fifty years. This rate of increase was not only continued, but came to be greatly exceeded in the present century.

Enumerations at eight census periods.

Since the first census of 1801, regular enumerations of the people of England and Wales have been taken every ten years. The results of these enumerations are shown in the subjoined table, giving the total numbers of the population at each census, together with the absolute increase, and the growth per cent., during each decennial period :—

Dates of Enumeration.	Population.	Increase at each census.	Decennial rate of increase per cent.
1801, March 10th........	8,892,536		
1811, May 27th..........	10,164,256	1,271,720	14·30
1821, May 28th..........	12,000,236	1,835,980	18·06
1831, May 29th..........	13,896,797	1,896,561	15·80
1841, June 7th..........	15,914,148	2,017,351	14·52
1851, March 31st........	17,927,609	2,013,461	12·65
1861, April 8th..........	20,066,224	2,138,615	11·93
1871, April 3d..........	22,712,266	2,646,042	13·19

Population in registration districts.

The increase of population throughout the century was larger in the towns than in the country districts. This was most markedly the case in the centennial period from 1861 to 1871, as will be seen from the following table, showing the increase per cent. of the population in each of the eleven "registration districts" mapped out by the registrar-general. It will be seen that the greatest increase was in the division, rich in manufacturing and mining industries, embracing the northern counties and Yorkshire, and the least in the agricultural districts of the south-western and eastern counties.

Divisions.	Population 1871.	Increase per cent. 1861–71.
I. London..................................	3,254,260	16
II. South Eastern (Surrey, Kent, Sussex, Hants, Berks).........	2,167,726	17
III. South Midland (Herts, Bucks, Oxford, Northampton, Hunts, Beds, Cambridge)...............	1,442,654	11
IV. Eastern (Essex, Suffolk, Norfolk)................................	1,218,728	7
V. South Western (Wilts, Dorset, Devon, Cornwall, Somerset)..	1,880,777	2
VI. West Midland (Gloucester, Hereford, Salop, Stafford, Worcester, Warwick)..........	2,720,669	11
VII. North Midland (Leicester, Rutland, Lincoln, Notts, Derby)..	1,406,935	9
VIII. North Western (Cheshire, Lancashire)	3,389,044	15
IX. Yorkshire..............................	2,395,569	19
X. Northern (Durham, Northumberland, Cumberland, Westmoreland)...........................	1,414,234	23
XI. Monmouth and Wales................	1,421,670	10
Total, England and Wales....	22,712,266	13

As regards sexes, the total numbers were as follows at each of the eight enumerations from 1801 to 1871 :—

Numbers of the Sexes.

Date of Enumeration.	Population.			
	Males.	Females.	Excess per cent. of Females.	Total.
1801	4,254,735	4,637,801	9·	8,892,536
1811	4,873,605	5,290,651	8·6	10,164,256
1821	5,850,319	6,149,917	5·1	12,000,236
1831	6,771,196	7,125,601	5·2	13,896,797
1841	7,777,586	8,136,562	4·6	15,914,148
1851	8,781,225	9,146,384	4·2	17,927,609
1861	9,776,259	10,289,965	5·2	20,066,224
1871	11,058,934	11,653,332	5·4	22,712,266

Census of 1871; area, houses, and population.

The following table exhibits the main results of the census of 1871 as regards extent and population, giving the area, in statute acres, of each of the forty counties of England and twelve counties of Wales, and the number of inhabited houses—a house being defined as a separate building inclosed by external and party walls—in each county. The population according to the census of 1861 is appended for the sake of comparison.

Counties or Shires.	Area in Statute Acres.	Inhabited Houses, 1871.	Population.

At the census of 1861 the number of inhabited houses was 3,739,505, so that there was an increase of 519,612 in the ten years. It was found at the census of 1871 that whereas in the whole of the United Kingdom there were

Divisions.	Persons to an inhabited House.	Persons to an Acre.	Acres to a Person.
England	5·4	0·66	1·52
Wales....................	4·9	0·26	3·88
England and Wales.	5·3	0·61	1·64

on the average 5·6 persons to each inhabited house, 0·41 persons to an acre, and 2·46 acres to a person, the proportions were very different in England and Wales. Expressed in tabular form, as most concise, they were as in preceding table.

England and Wales are at present more densely populated than any country of Europe, except Belgium. Taking the whole of the United Kingdom, the average density of population in 1871 was 265 individuals per square mile; but while the proportion in Scotland was only 109, and in Ireland 169 per square mile, in England and Wales it was 389 inhabitants per square mile.

Growth of population in the country.

The growth of population leading to the present high density has been of comparatively recent date. A succinct survey of it is given in the subjoined table, showing the estimated population of England and Wales, at the end of June every fifth year from 1801 to 1876, and also for 1877, according to the returns of the registrar-general.

Years. June 30th.	Males.	Females.	Total.
1801	4,404,490	4,656,503	9,060,993
1806	4,700,476	4,955,643	9,656.119
1811	5,025,212	5,297,380	10,322,592
1816	5,474,848	5,721,308	11,196,156
1821	5,946,821	6,158,793	12,105,614
1826	6,417,196	6,657,090	13,074,286
1831	6,859,085	7,135,375	13,994,460
1836	7,310,074	7,618,403	14,928,477
1841	7,784,883	8,144,609	15,929,492
1846	8,298,360	8,645,732	16,944,092
1851	8,808,662	9,174,187	17,982,849
1856	9,311,182	9,731,230	19,042,412
1861	9,801,152	10,318,162	20,119,314
1866	10,427,146	10,982,538	21,409,684
1871	11,093,123	11,689,689	22,782,812
1876	11,801,633	12,442,377	24,244,010
1877	11,948,677	12,598,632	24,547,309

It will be seen that the annual increase from the beginning of the century till the middle of 1877 was at the average rate of 1·35 per cent., being considerably above that of any other country in Europe.

Population in boroughs and rural districts.

The general increase of population was, as before noticed, far greater in the towns than in the rural districts. This was specially the case in the twenty years from the census of 1851 to that of 1871, as shown in the subjoined table.

Census Year.	Parliamentary Boroughs.	Districts outside Parliamentary Boroughs.	Total.
1851	7,438,679	10,488,930	17,927,609
1861	8,638,569	11,427,655	20,066,224
1871	10,652,423	12,059,843	22,712,266
	Actual increase in the two Periods.		
1851–61	1,199,890	938,725	2,138,615
1861–71	2,013,854	632,188	2,646,042
	Increase per cent.		
1851–61	16·1	8·9	11·9
1861–71	23·3	5·5	13·2

Population of large towns.

At the end of June, 1877, the population of the 13 largest towns in England and Wales, each with over 100,000 inhabitants, was as follows, according to the estimates of the registrar-general, based upon the returns of births and deaths:—London, 3,533,484 inhabitants; Liverpool, 527,083; Manchester, with Salford, 500,397; Birmingham, 377,436; Leeds, 291,580; Sheffield, 274,914; Bristol, 199,539; Bradford, 173,723; Newcastle-on-Tyne, 139,929; Hull, 136,933; Portsmouth, 124,867; Leicester, 113,581; and Sunderland, 108,343 inhabitants. One-fourth of the total urban population of England and Wales live in London, and not far from one-third live in 18 large cities and towns, selected by the registrar-general for the publication of weekly rates of mortality. The following is a list of these 18 towns, all of them containing over 60,000 inhabitants, with their population at the censuses of 1861 and 1871, and the rate of increase per cent. during the decennial period.

Cities and Towns.	1861. April 8.	1871. April 3.	Rate of increase per cent.
London	2,803.989	3,254,260	16·1
Liverpool	443.938	493,405	11·1
Manchester	338.722	351,189	3·7
Salford	102,449	124,801	21·8

Vital statistics.

While the eight decennial census enumerations, from 1801 to 1871, bear witness to the rapid growth of population in England and Wales, the favorable vital statistics of the country are no less distinctly shown by the annual returns of the registrar-general compiled from the registers of births, deaths, and marriages. These registers, in use, though not general, since the reign of Queen Elizabeth, were formerly a part of the ecclesiastical organization, and continued to be attached, more or less, to the church till the year 1837, at the commencement of which an Act of Parliament came into operation which provided a far more complete machinery than that before existing for the exact record of all births, deaths, and marriages. The new system—established eighteen years earlier than a similar one for Scotland—which relieved the clergy from the functions previously thrown upon them, was still more improved by subsequent Acts, one of the most important of which, making all registration of births and deaths compulsory, came into operation on the 1st of January, 1875. It is generally held that the present system is as perfect as that of any country in Europe.

The following table gives the annual numbers of births, deaths, and marriages in England and Wales for every fifth year from 1841—when the improved system had been brought into full organization—to the year 1876:—

Births, Deaths, and Marriages, 1841 to 1876.

Years.	Births.	Deaths.	Marriages.
1841	512,158	343,847	122,496
1846	572,625	390,315	145,664
1851	615,865	395,396	154,206
1856	657,704	391,369	159,262
1861	696,406	435,114	163,706
1866	753,870	500,689	187,776
1871	797,428	514,879	190,112
1876	887,464	510,308	201,835

The rate of births, deaths, and marriages for each 1000 of the population of England and Wales, computed on the estimated number for the middle of each of the same years was as follows:—

Years.	To 1000 Persons living.		
	Births.	Deaths.	Persons Married.
1841	32·2	21·6	15·4
1846	33·8	23·0	17·2
1851	34·2	22·0	17·2
1856	34·5	20·5	16·7
1861	34·6	21·6	16·3
1866	35·2	23·4	17·5
1871	35·0	22·6	16·7
1876	36·6	21·9	17·0
Mean average	34·0	22·3	16·5

Taking the average of the whole period of 37 years, from 1841 to 1876, there was one birth annually to every 29 persons, one death to every 45 persons, and one individual married to every 61 persons. The highest birth rate was in 1847, when there was one birth to 32 persons; the lowest death rate in 1845 and 1850, when there was one death to 48 persons; and the highest marriage rate in 1853, when one individual was married to every 56 persons.

Proportion of the sexes.

The proportion of the sexes born—not quite regular throughout the period, but with a marked tendency to male decrease—was that of 104,811 boys to every 100,000 girls. The disproportion in the excess of male births has been ascertained to find its equilibrium, through a higher rate of infant mortality among the males, about the tenth year of life, and is finally changed, by perilous male occupations and other causes, to the extent that there are 100,000 women of all ages to 94,900 men in England.

Illegitimacy.

The number of illegitimate births underwent a gradual decline in the period from 1840 to 1876, which was greatest in the last decade. The average annual number of illegitimate births to every 100 births was 5·7 in the ten years from 1865 to 1874, and fell to 5·0 in 1875, and to 4·8 in 1876. The rate of illegitimacy was highest in the agricultural counties, where it increased in recent years, while largely decreasing in the urban districts. The increase was highest in Essex, where it rose to 10·5 per cent.; in Hertfordshire, where it rose to 17·3 per cent.; and in Rutlandshire, where it went as high as 23·5 per cent., so that in the latter purely agricultural county nearly one-fourth of all the births were illegitimate.

Early marriages.

It seems probable that the decrease of illegitimacy in the urban districts is much influenced by a constantly increasing number of early marriages. While in the quinquennial period 1841–45 the proportion of males under age that married was 4·38 per cent., and of females 13·33 per cent., the marriage rate of minors, undergoing a steady and uninterrupted rise, went up in the period 1871–75 to 8·15 for males and to 22·22 for females. In the ten years from 1846 to 1855, the proportion of males under age who married was 10·64 per cent., and of females under age 33·47, while in the ten years from 1866 to 1875, the proportional percentage was 17·05 for men and 47·09 for women.

Vital statistics of England compared with foreign countries.

The rates of births, deaths, and marriages in England and Wales compare very favorably with those of most Continental countries. While the average annual birth rate in the twenty years from 1856 to 1875 was higher in some states, such as Prussia and Austria, the annual death rate during the same period was much lower, resulting in a larger actual surplus of births over deaths. As regards the average marriage rate within the period, that of England and Wales was not as high as in some Continental counties; but this again was more than compensated for by a greater fecundity of marriages. Taking the total increase of population within the century, England stands at the head of the list—France being at the bottom—of all the states of Europe.

Emigration.

The increase of population would have been still greater, but for the disturbing element of emigration. It was soon after the cessation of the Napoleonic wars that the emigration movement from the United Kingdom began, setting in at first very feebly, and being directed almost solely towards the United States of America. It gained intensity during the decade from 1841 to 1850; and, gradually rising, reached its highest point in 1851 and 1852, in which years respectively 335,966 and 368,764 persons left the kingdom. After this there was a gradual decline in the number of British emigrants till 1861, when it sank to 91,770, which decrease was followed, with changes, by a further rise, and then by a final decline, lasting to the present time.

Emigrants from England and Wales.

In the returns of emigration issued by the Government, no distinction of nationalities was made previous to the year 1853; and it cannot be stated, therefore, how many of the emigrants who left the country from 1815 to 1853 were natives of England and Wales. In the eight years from 1853 to 1860 the number of English emigrants was 195,684, and in the ten years 1861 to 1870 it rose to 365,115. In 1871 the number was 71,926, and in 1872 it rose to 82,339. The number fell 78,968 in 1873, to 56,338 in 1874, to 43,867 in 1875, and to 34,612 in 1876. During the whole of the twenty-four years from 1853 to 1876 the number of emigrants from England and Wales was 928,898, out of the total emigration of 4,961,350. The proportion of English emigrants was thus less than one-fifth, and assuming the same to have been the case during the whole period, it may be calculated that about a million and a half of natives of England and Wales quitted the country in the sixty-two years from 1815 to 1876, which formed the emigration period.

Emigrants from 1815 to 1876.

The following table gives a survey of the emigration from the United Kingdom to foreign countries, in groups of years and single years, distinguishing two great periods of rise and fall, from 1815 to 1852 and from 1853 to 1876:—

Years.	Number of Emigrants.	Years.	Number of Emigrants.
1815–1820..........	123,528	1853–1860..........	1,582,475
1821–1830	247,292	1861–1870..........	1,976,570
1831–1840..........	703,150	1871..................	252,435
1841–1850..........	1,684,892	1872..................	295,213
1851..................	335,966	1873..................	310,612
1852..................	368,764	1874..................	241,014
		1875...	173,809
		1876..................	138,222
Total, 1815–1852.	3,463,592	Total, 1853–1876.	4,961,350

During the whole of the two periods, embracing sixty-two years, the total number of emigrants that left the United Kingdom was 8,424,042.

Emigrants and immigrants.

The period all but closed with 1876, in which year the surplus of British emigrants over returning immigrants was reduced to the small number of 17,822. Since the year 1870, but not previously, tolerably accurate accounts are kept of immigration as well as emigration, with the results shown in the following table, which gives for the seven years from 1870 to 1876 the number of emigrants of British origin, together with the number of immigrants, with the balance of net emigration.

Years.	Number of British Emigrants.	Number of Immigrants.	Net Emigration.
1870	202,511	49,157	153,354
1871	192,751	53,827	138,924
1872	210,494	70,181	140,313
1873	228,345	86,416	141,929
1874	197,272	118,129	79,143
1875	140,675	94,228	46,447
1876	109,469	91,647	17,822

Destination of emigrants.

The British emigration of 1876 was made up of 73,396 persons of English, 10,097 of Scottish, and 25,976 of Irish origin. Of the English emigrants, 34,612 went to the United States, 6227 to British North America, 20,582 to Australia, and 11,975 to other colonies and other foreign countries. More persons of British origin returned from the United States than went there in the year 1876, the number of emigrants being 54,554, and of immigrants 54,697. On the whole, it seems probable that the emigration movement will not soon again rise to the vast dimensions it once assumed, and that, at any rate, it will cease to be an important factor in the growth of the English population.

III. *Division of the Land.—Agriculture.*

Division of landed property.

Till within the last few years nothing whatever was known regarding the ownership of land in England, and widely differing estimates, none of them of any real value in the absence of all authentic facts, were brought forward from time to time about the subject. Various attempts to get official returns failed, till at last the House of Lords consented to an inquiry, which resulted in the publication, in 1876, of a report in two volumes imperial quarto, entitled *Landowners in England and Wales: Return of the Owners of Land of One Acre and upwards in England and Wales, exclusive of the Metropolis, with their Names, Addresses, Extent of Lands, and Estimated Gross Rental.* Though the information put forth in this Bluebook, referring to the year 1873, is not distinguished by great accuracy, the returns regarding the extent and rental of the land being based on the parish valuation lists, mostly very defective, while large extents of land are not accounted for at all, still the publication proved of the highest interest, as containing the only actual facts known about the division and ownership of the land.

Number of land-owners in 1873.

The summary of the return published by the Government, referred to frequently as the New Domesday Book, showed that in the year 1873 there were in England and Wales 972,836 owners of land, holding together 23,013,515 acres, of a gross estimated rental of £99,382,301. The subjoined table exhibits the number of landowners, under thirteen classifications of ownership, the total extent of lands held by each class, and the gross estimated rental:—

Classification of Ownership.	Number.	Extent of Lands.	Gross Estimated Rental.
		Acres.	£
Less than one acre	703,289	151,172	29,127,679
1 acre and under, 10	121,983	478,680	6,438,325
10 acres and " 50	72,640	1,750,080	6,509,290
50 " " 100	25,839	1,791,606	4,302,003
100 " " 500	32,317	6,827,347	13,680,760
500 " " 1,000	4,799	3,317,678	6,427,552
1,000 " " 2,000	2.719	3,799,307	7,914,371
2,000 " " 5,000	1,815	5,529,190	9,579,312
5,000 " " 10,000	581	3,974,725	5,522,610
10,000 " " 20,000	223	3,098,675	4,337,023
20,000 " " 50,000	66	1,917,076	2,331,303
50,000 " " 100,000	3	194,939	188,746
100,000 and upwards	1	181,616	161,874
Areas not specified	6,448	...	2,831,453
Rentals "	113	1,424	...
Total of England and Wales (exclusive of the Metropolis)	972,836	33,013,515	99,352,301

Of the total area of England and Wales, comprising 37,324,883 statute acres, no less than 4,311,368 are not accounted for in the foregoing returns. These must consist partly of waste spaces, moorlands, and other areas, including that of the metropolis and crown property, intentionally set aside; and partly of lakes, rivers, and roads. This leaves perhaps a million or more of acres wanting, through great errors and omissions in the parish lists on which the returns were based. Still, with all these imperfections, and the undoubted miscalculations in the rental values, generally admitted to be large under-statements, enough remains to give a fair idea of the division of landed property in England and Wales.

Great and small land-owners.

One of the most notable features of the returns is the fact that the number of landowners possessed of less than one acre is as high as 703,289, being 73·3 per cent. of the whole. The great decrease seen in the number of those who possess from one acre to ten, being considerably under one-fifth of the first class, is remarkable; and no less so is it that there are more landowners who possess from 100 to 500 acres than who possess from 50 to 100 acres. The total number of landowners in England and Wales is altogether, according to these returns, very far above what was formerly believed, for in the census returns of 1861 the number of "landed proprietors" was given at 30,766, and in those of 1871 at 22,964. But while it is seen that real property is so widely distributed, there appears not the less from the Bluebook of 1876 the all-important fact that the proprietors of over 5000 acres, who deserve, more especially, the title of "great" landowners, 874 in number, hold 9,367,031 acres, or more than one-fourth of the country. The owners of 1000 acres and upwards, numbering 5408, hold 18,695,528 acres, being more than one-half of the land; and those of 500 acres and upwards, 10,207 in number, hold 22,013,206 acres, or two-thirds of the whole of England and Wales.

English, Scottish, and Irish land-owners.

Together with the returns of landowners in England there were issued similar ones for Scotland and Ireland. It is not a little interesting to compare the relative facts given in these various returns, which illustrate to a striking degree the diversity of the ownership of the soil and division of the land in the three portions of the United Kingdom. While in England the proportion of landowners below an acre is 73·3 per cent., it is 85·5 per cent. in Scotland, and 52·6 in Ireland. Again, of landowners possessing more than one acre, the proportion who have less than 500 acres is 96·1 per cent. in England, 86·5 per cent. in Scotland, and 80·1 per cent. in Ireland. With regard to England, the twelve largest owners hold in the aggregate 1,058,883 acres, while the twelve largest owners in Scotland possess 4,339,722 acres, and the twelve largest owners in Ireland 1,297,888 acres. Thus the ownership of the twelve principal landowners of England is not one-fourth that of the twelve chief landowners of Scotland.

The total number of landowners in each of the divisions of the United Kingdom was given as follows in the official returns:—

Divisions.	Number of Owners of less than one acre.	Number of Owners of one acre and upwards.	Total Number of Owners.
England	703,289	269,547	972,836
Scotland	113,005	19,126	132,131
Ireland	36,144	32,572	68,716
United Kingdom	852,438	321,245	1,173,683

The gross estimated rental value of the landed property enumerated in the returns was stated as follows:—

Estimated Rental Value of Land.

Divisions.	Estimated Rental value.
England..........................	£99,352,301
Scotland..	18,698,774
Ireland...	13,417,758
United Kingdom..............................	£131,468,833

Land population, and houses.

In England, one person in 20 of the population is an owner of land, against one in 25 in Scotland, and one in 79 in Ireland. The proportion of owners of land to inhabited houses is 1 to 4 in England, 1 to 3 in Scotland, and 1 to 14 in Ireland. In England, the average extent of land held by each owner is 33 acres 3 roods 30 perches, while it is 143 acres 1 rood 6 perches in Scotland and 293 acres 1 rood 32 perches in Ireland. The average estimated rental of each owner of land in England is £102, 3s., against £141, 8s. in Scotland, and £195, 3s. in Ireland.

The "upper ten thousand."

According to the New Domesday Book, about two-thirds of the landed property accounted for in the returns as existing in England and Wales is held by 10,207 owners, who, therefore, well deserve the old title of the "upper ten thousand." The following proprietors outside the metropolis are returned in 1873 as either holding upwards of 50,000 acres, or having estimated rentals exceeding £100,000 per annum:—

Proprietor.	County.	Acres.	Rental.
			£
Duke of Northumberland	Northumberland........................	181,616	161,874
Duke of Devonshire	Derby, York (W. R), Lancaster, Sussex.	126,904	127,633
Sir W. W. Wynn, Bart..	Denbigh, Montgomery, Merioneth......	87,256	42,882
Duke of Cleveland......	Durham, Salop........................	81,441	61,824
Earl of Carlisle.......	Cumberland, Northumberland, York (N. R.)............	78,540	49.601
Duke of Bedford........	Bedford, Cambridge, Devon............	74,996	127,653
Earl of Lonsdale	Westmoreland, Cumberland.	67.457	69,959
Earl of Powis	Montgomery, Salop.....................	60,531	6[illegible],694
Duke of Rutland........	Leicester, Derby.......................	57,982	70,998
Earl of Derby	Lancaster, Derby.......................	56,471	163,195
Earl of Yarborough.....	Lincoln..................................	55,272	76,226
Lord Leconfield.........	Sussex, York (E. R.), Cumberland	54,615	51,940
Marquis of Ailesbury...	Wilts, York (N. R.).....................	53,362	58,030
Earl Cawdor............	Carmarthen, Pembroke.................	51,517	34,987
Sir Lawrence Palk, Bart.	Devon..................................	10.109	109,275
Sir J.W. Ramsden, Bart.	York (W. R.)............................	8,589	167,601

In some cases the estimated rental exceeds the income derived from the property. The average estimated rental value of the whole of the land is given at £3, 0s. 2d. per acre, which is thrice that of Scotland, where the average is 19s. 9d. per acre, and four and a half times as much as in Ireland, where it is 13s. 4d. per acre. The comparatively high rental of the land in England and Wales, combined with the limited ownership of the soil, two-thirds being in the hands of little over ten thousand persons, and the rest divided among nearly a million, must have naturally the greatest influence on the state of agriculture of the country. To what extent this is the case, will be seen from the "Agricultural Returns" annually published by the Government.

Division of land in the official agricultural returns.

These returns, drawn up under a well-organized system, on the basis of information regularly furnished by the occupiers of the land to the officers of the inland revenue, divide the whole of England exclusive of Wales, into two great districts, the first being called the Western or "the Grazing division," and the second the Eastern or "the Corn-growing division," viz.:—

Grazing Counties.

- Northumberland.
- Cumberland.
- Durham.
- York, North and West Ridings.
- Westmoreland.
- Lancashire.
- Cheshire.
- Derby.
- Stafford.
- Leicester.
- Shropshire.
- Worcester.
- Hereford.
- Monmouth.
- Gloucester.
- Wilts.
- Dorset.
- Somerset.
- Devon.
- Cornwall.

Corn Counties.

- York, East Riding.
- Lincolnshire.
- Nottingham.
- Rutland.
- Huntingdon.
- Warwick.
- Northampton.
- Cambridge.
- Norfolk.
- Suffolk.
- Bedford.
- Bucks.
- Oxford.
- Berks.
- Hants.
- Hertford.
- Essex.
- Middlesex.
- Surrey.
- Kent.
- Sussex.

Although the number of counties is nearly the same in each of these two groups, the total average is larger in the grazing than in the corn division in the ratio of 53 to 47 per cent. of total acreage under crops and grass in England.

Returns of the grazing and corn-growing counties.

The following tables furnish a concise account of the acreage under crops and otherwise, together with the number of live stock, in the two divisions of grazing and corn-growing counties of England, according to the Agricultural Returns for the year 1877:—

	Grazing Counties.		Corn Counties.	
	Acreage.	Percentage of total.	Acreage.	Percentage of total.
Total acreage returned..	12,908,018	53·1	11,404,015	46·9
Wheat	1,047,077	35·1	1,940,052	64·9
Barley	724,679	36·2	1,275,852	63·8
Oats	777,215	52·2	712,784	47·8
Rye	15,800	32·5	32,804	67·5
Beans	126,851	27·0	343,302	73·0
Peas	69,820	22·8	236,536	77·2
Total corn crops	2,761,442	37·8	4,541,330	62·2
Potatoes	179,013	58·9	124,951	41·1
Turnips and swedes	679,234	45·4	816,651	54·6
Mangold	101,529	29·2	246,760	70·8
Carrots	3,054	21·1	11,391	78·9
Cabbage, rape, etc	69,120	39·2	107,098	60·8
Vetches, lucerne, etc	125,367	29·8	295,006	70·2
Grass under rotation. for hay	810,654	50·4	798,703	49·6
Grass under rotation. not for hay.	673,958	59·7	454,072	40·3
Total green crops and grass	2,641,929	48·1	2,854,632	51·9
Bare fallow	251,459	43·6	324,776	56·4
Permanent pasture for hay	2,033,187	62·8	1,206,178	37·2
Permanent pasture not for hay.	5,208,654	68·4	2,409,997	31·6
Flax	2,845	39·5	4,365	60·5
Hops	8,502	11·9	62,737	88·1
Orchards, etc	122,499	77·0	36,596	23·0
Woods, etc	676,139	51·0	649,626	49·0
LIVE STOCK.				
Horses, for agriculture..	365,664	48·0	395,425	52·0
Do., unbroken, and for breeding..	171,075	55·3	138,044	44·7
Cattle	2,621,282	65·9	1,358,368	34·1
Sheep	9,697,359	52·9	8,633,018	47·1
Pigs	1,028,734	48·6	1,086,017	51·4

The following short statement gives a summary of the preceding table, showing the percentage of the distribution of the acreage for each division:—

	Grazing Counties.	Corn-growing Counties.
	Percentage of Total Acreage in the Division.	Percentage of Total Acreage in the Division.
Acreage under—		
Corn crops	21·4	39·8
Green crops	9·0	14·0
Clover and other grass under rotation for hay	6·3	7·0
Clover and other grass under rotation not for hay	5·2	4·0
Bare fallow	1·9	2·8
Permanent pasture for hay	15·7	10·6
Permanent pasture not for hay	40·4	21·1

Distribution of the acreage of England and Wales.

In the returns of the census of 1871, before given, the total area of England was stated at 32,590,397 acres, and that of Wales at 4,734,436 acres. In the Agricultural Returns for the year 1877 it was reported that the total acreage under crops, bare fallow, and grass had come to be 24,312,033 acres in England, and 2,731,159 acres in Wales. Thus there were 8,278,364 acres, or about one-fourth of the total, not accounted for in the Agricultural Returns for England, and 1,643,327 acres, or about one-third of the total, in those for Wales. The subjoined tables exhibit the distribution of the acreage, and the numbers of live stock, both for England and for Wales in the year 1877.

Crops.	England.	Wales.
Corn crops:	Acres.	Acres.
Wheat	2,987,129	100,226
Barley or bere	2,000,531	147,212
Oats	1,489,999	239,298
Rye	48,604	1,455
Beans	470,153	2,979
Pease	306,356	3,508
Total of corn crops.	7,302,772	494,678
Green crops:—		
Potatoes	303,964	42,942
Turnips and swedes	1,495,885	70,813
Mangold	348,289	7,713
Carrots	14,445	376
Cabbage, kohl-rabi, and rape	176,218	1,305
Vetches and other green crops except clover or grass	420,373	6,386
Total of green crops	2,759,174	129,535
Clover, sanfoin, and grasses under rotation:—For hay	1,609,357	207,012
Not for hay	1,128,030	144,785
Total of clover, etc	2,737,387	351,797
Permanent pasture or grass not broken up in rotation (exclusive of heath or mountain land):—		
For hay	3,239,365	399,194
Not for hay	7,618,651	1,333,089
Total of permanent pasture, etc	10,858,016	1,732,283
Flax	7,210	28
Hops	71,239	
Bare fallow or uncropped arable land	576,235	22,838
Total acreage under crops, bare fallow, and grass	24,312,033	2,731,159

It appears from the last annual Agricultural Returns that the extent of arable land in England and Wales is on the decrease, as is also the produce of live stock, while, on the other hand, the area of pasture land is on the increase. The decline in the acreage of arable land, very marked in the five years from 1872 to 1877, was greater in Wales than in England, and embraced all the principal crops.

Live Stock in England and Wales.

Live Stock.	England.	Wales.
	Number.	Number.
Horses, including ponies :—		
Used for purposes of agriculture	761,089	71,043
Unbroken horses and mares kept solely for breeding.	309,119	58,595
Total of horses	1,070,208	129,638
Cattle :—		
Cows and heifers in milk or in calf	1,557,574	254,392
Other cattle :—		
2 years of age and above	1,072,407	120,355
Under 2 years of age	1,349,669	241,462
Total of cattle	3,979,650	616,209
Sheep :—		
1 year old and above	11,481,945	1,974,313
Under 1 year old	6,848,432	887,700
Total of sheep	18,330,377	2,862,013
Pigs	2,114,751	230,720

Decrease of the extent of arable land, and increase of pastures.

The land under wheat fell from 3,336,888 acres in 1872 to 2,987,129 in 1877, in England; and from 126,367 acres in 1872 to 100,226 in 1877, in Wales. During the same period, the acreage under potatoes fell in England from 339,056 to 303,964, and in Wales from 48,417 to 42,942; and that under clover in England from 2,822,392 to 2,737,387, and in Wales from 370,850 to 351,797. In the acreage under barley and oats there was a slight increase in England, but a decrease in Wales; while in the acreage under turnips and swedes there was a trifling increase in England and a decrease in Wales during the period. Taken altogether, the extent of arable land in England fell from 13,839,000 acres in 1872 to 13,454,000 acres in 1877, being a decrease of 385,000 acres. In Wales, the extent of arable land sank from 1,104,000 acres to 999,000 acres in the same period, the decrease amounting to 105,000 acres. The decrease of arable land during the five years was very steady, and so likewise was the increase in the acreage of pasture land. There were in England under pasture—exclusive of heath and mountain land—9,991,000 acres in 1872, and 10,858,000 acres in 1877, the increase in the five years amounting to 867,000 acres, being more than double the extent of decrease of arable land. In Wales there were under pasture 1,532,000 acres in 1872, and 1,732,000 acres in 1877, making the increase amount to 200,000 acres, this also being not far from double that of the decrease in arable land. The decrease in the extent of arable land, and simultaneous increase of pastures, may be explained by the fact of England being supplied, more and more, with corn from foreign countries, where it can be grown cheaper than at home. Naturally, the produce of pasture lands cannot be brought in the same way into the country.

Diminution of live stock in 1874–77.

If the decrease of arable land and increase of pastures can be thus explained, it is not so easy to account for the decline of live stock which also took place during the same period, more especially from 1874. It might have been expected that the widening of the pastural area would have led to an increase of live stock, but the contrary was the case, more especially as regards horned cattle and sheep. In England there were 4,305,440 head of cattle in June, 1874, and 3,979,650 head in June, 1877, so that there was a decrease of 325,790 head in three years. During the same period, the number of cattle in Wales fell from 665,105 to 616,209, being a decline of 48,896. The decrease in numbers was even greater in sheep. There were 19,859,758 sheep in England in June, 1874, and 18,330,377 in June, 1877, being a decrease of 1,529,381. In Wales, during the same period, the number of sheep fell from 3,064,696 to 2,862,013, being a decrease of 202,683. Thus the total decline in the number of sheep in England and Wales was no less than 1,732,064 in the short space of three years. The great diminution of live stock during the triennial period from 1874 to 1877 was not confined to England and Wales, but occurred simultaneously in Scotland, as well as in Ireland, being greatest in the latter country, where the decline in sheep alone amounted to 10¼ per cent.

Number of agriculturists.

In the census returns of 1871, the number of persons entered as "agriculturists" in England and Wales was 1,447,481, comprising 1,264,031 men and 183,450 women. At the preceding census (1861) the number of "agriculturists" was given at 1,833,652, showing a diminution of 386,171 within the decennial period, due probably to the augmented use of machinery for the cultivation of the soil.

IV.—*Mines and Minerals.*

Mineral riches of Great Britain in 1876.

Next to agriculture, first foundation of the wealth of all countries, the material resources of England lie in its minerals. The earliest traces of its mineral riches appear in the visits of men from the Mediterranean, who braved the dangers of unknown seas to gather the tin of Cornwall. Cornish tin still holds the first place in the annual reports on the "Mineral Statistics of the United Kingdom" drawn up by the keeper of mining records; but, though by no means an unprolific source of riches, it has sunk far behind a number of other minerals, unknown, even in name, at the time the Phœnicians visited, in search of it, the island of Britain. In the last of these annual reports the mineral produce of Great Britain is summarized as follows, in regard to quantities and value, under nineteen headings, or classes, representing the produce of the year 1876:—

Minerals.	Quantities.		Value.
	Tons.	Cwts.	£
Coal	133,344,766	0	46,670,668
Iron ore	16,841,583	14	6,825,705
Copper ore	79,252	0	317,186
Tin ore	13,688	9	600,923
Lead ore	79,096	6	1,218,078
Zinc ore	23,613	8	90,142
Iron pyrites	48,809	14	43,870
Arsenic	4,228	1	28,092
Manganese	2,796	17	9,783
Ochre and umber	3,805	4	4,478
Wolfram	23	10	172
Fluor spar	337	10	230
Clays	3,971,123	0	744,224
Oil shales	610,785	0	319,853
Salt	2,273,256	0	1,136,628
Barytes	23,561	18	24,479
Coprolites	258,150	0	625,000
Gypsum	61,741	0	13,571
Sundry minerals, including China stone	......		13,750
Total value of minerals produced in 1876			58,691,832

Total value of minerals and metals.

Under another calculation, the keeper of mining records gives the following summary of the total value of minerals, together with metals, obtained from the mines of the United Kingdom in 1876:—

Coal	£46,670,668
Metals, obtained from ores	18,668,818
Earthy and other minerals	2,887,367
Total value	£68,226,853

Metals produced in 1876.

The metals obtained from ores are classified as follows, according to quantities and value, in 1876:—

Metals.	Quantities.	Value.
	Tons.	£
Pig iron	6,555,997	16,062,192
Lead	58,667	1,270,415
Tin	8,500	675,750
Copper	4,694	392,300
Zinc	6,641	158,011
	Ounces.	
Silver	483,422	106,262
Gold	293	1,138
Other metals	......	2,750
Total value	......	18,668,818

Chief articles of British mineral produce.

It will be seen by a glance at the preceding tables that the mineral wealth of the United Kingdom lies, in substance, in two articles, namely, coal and iron ore. From these springs, as immediate produce, a third, namely, pig iron. Coal and iron ore together form, as regards value, over nine-tenths of the mineral produce; while pig iron by itself holds nearly the same position in value among the metals produced in the United Kingdom.

Coal produce of England and Wales.

Coal.—In the production of the by far most important article of Great Britain's mineral wealth, to which all others are but appendages, England and Wales stand foremost to such an extent as to throw the other two divisions of the United Kingdom into comparative insignificance.[1] To the total coal produce of the United Kingdom in the year 1876, England and Wales contributed 114,554,278 tons, being five-sixths of the whole. The remainder, 18,790,488 tons, was produced almost entirely in Scotland,—the mines of East Scotland furnishing 11,667,648 tons, and those of West Scotland 6,997,904 tons. The production of coal in Ireland in 1876 was not more than 124,936 tons.

Colliery districts and their production.

England and Wales are officially divided into nineteen colliery districts, very unequal in size, but so arranged, geographically, as to be within the constant and regular inspection of the Government survey. The following table gives a list of these districts, with the number of collieries in each, and the quantities of coal taken from them in the year 1876.[2]

Colliery Districts.	Number of Collieries.	Coal produce in 1876.
		Tons.
North Durham and Northumberland	183	12,580,500
South Durham	185	19,411,123
Cumberland and Westmoreland	42	1,401,603
Cheshire	39	584,380
Lancashire, North and East	385	8,265,000
Lancashire, West	174	9,125,000
Yorkshire	562	15,055,275
Derbyshire	261	7,025,350
Nottinghamshire	48	3,415,100
Warwickshire	29	884,750
Leicestershire	27	1,005,000
Staffordshire, South, and Worcestershire	434	10,081,067
Staffordshire, North	152	4,077,548
Shropshire	64	1,054,049
Gloucestershire	89	1,257,547
Somersetshire	45	650,415
Monmouthshire	134	4,499,985
Wales, North	128	2,207,250
Wales, South	400	11,973,336
Total	3,381	114,554,278

England's resources in coal.

Seeing the supreme importance of coal as the chief material agent of modern civilization, and one the value of which, instead of lessening, is likely to become infinitely greater in future years with the expansion of science and arts, the question has frequently been discussed whether the British coal-fields may not become exhausted at some time or other. The subject more especially engaged the attention of parliament and the Government in 1866, through the publication of a work by Professor W. Stanley Jevons, of Manchester, entitled *The Coal Question*, which, while admitting the immensity of England's wealth in coal, asserted that the present ever-increasing rate of supply could not continue in the same proportion for any great length of time. This theory found much opposition, others maintaining that the coal deposits of Great Britain were virtually inexhaustible, and that properly managed, and with constantly improved scientific appliances, their riches would last as long as, if not longer than, the probable life of the nation.

The discussion in and out of parliament on "the exhaustion of our coal mines," important as it was, scarcely settled the main points of the question, namely, first to what depth the coal mines of Great Britain can be practically worked, and, secondly, to what extent the use of coal may be limited in the future, by the discovery of other motive powers. As to the first point, Mr. Edward Hull, a well-known authority on mining subjects, laid it down, after practical inquiries, that the limit of coal-mining was not reached till the depth of 4000 feet; but this again was disputed by other investigators, who expressed confidence that the limit was 2500 feet, a depth already reached in some existing mines. Greater still must be the uncertainty regarding the possible or probable discovery of other sources of motive power as substitutes for coal. The opponents of the widely expressed theory that such discoveries were not only possible, but of the very nature of scientific progress, which having, quite recently, taught mankind the high value of coal, was not likely to stop here, found powerful support in Professor Tyndall, who insisted that coal was the absolute monarch, present and future. "I see no prospect," he wrote to Professor Jevons, "of any substitute being found for coal as a motive power. We have, it is true, our winds and streams and tides; and we have the beams of the sun. But these are common to all the world. We cannot make head against a nation which, in addition to these sources of power, possesses the power of coal." Professor Tyndall concludes with the somewhat startling dictum that "the destiny of this nation is not in the hands of its statesmen, but of its coal-owners," adding, emphatically, that "while the orators of St. Stephen's are unconscious of the fact, the life-blood of this country is flowing away."

Increase in the production of coal, 1855 to 1876.

Professor Tyndall wrote this letter in 1866; and if, as he and others thought, the "life-blood of this country" was then flowing at too high a rate, it has been flowing much faster ever since. In the ten years from 1856 to 1866, the production of the coal mines of the United Kingdom rose from 66,645,450 tons to 101,630,544, and after another lapse of ten years, in 1876 it had risen to 133,344,766 tons. The gradual rise in production is indicated in the subjoined table, which shows the quantities and the value of the coal brought from the mines of the United Kingdom every third year from 1855, when the first accurate returns were published, to 1876:—

Years.	Quantities.	Value.
	Tons.	£
1855	61,453,079	16,113,267
1858	65,008,649	16,252,162
1861	83,635,214	20,908,803
1864	92,787,873	23,197,968
1867	104,500,480	26,125,145
1870	110,431,192	27,607,798
1873	127,016,747	47,631,280
1876	133,344,766	46,670,668

It is an admitted fact that the price of coal, which has been gradually rising in recent years, must continue to rise, both on account of its increased consumption, and of the constantly growing expenses of raising it. Although the total area of the coal-fields of Great Britain extends, according to the most authentic estimates, over 5400 square miles, comparatively few new pits have been opened in recent years; and the ever increasing demand has been supplied by the deepening, as well as widening, of the best collieries. This could only be achieved at an increased outlay, inasmuch as the cost of raising coal to the surface and the attendant expenses of administration and supervision are far greater than the cost of the actual displacement of the material from its beds.

Distribution of work in collieries; accidents.

From the returns of one of the oldest and best managed collieries in England, the South Hetton, in Durham, it appears that out of 529 men employed, only 140 were hewers of coal. The account, interesting in various ways, stands as follows:—

	Persons.
Hewers of coal	140
Putters, screeners, and loaders	227
Administrative staff	123
Miscellaneous workers	39
Total number of persons employed in colliery	529

The extraordinarily large number of persons required in a colliery, over and above the actual producers of coal, to attend to the working of the establishment, is explained by the mine and its machinery requiring the most strict and unceasing supervision to prevent dangerous accidents. Thus a large staff of workmen and artisans of all kinds, such as smiths, joiners, engine-wrights, masons, and others, has to be kept, to watch over the complicated apparatus by which the mine is ventilated and the precious mineral raised from the bowels of the earth. It may be said that, as a rule, the working of the collieries of England and Wales is most satisfactory, the superintendence, both on the part of the private owners and the Government, being the best that human ingenuity can devise. Nevertheless, the annual loss of life is terribly large. In the ten years from 1857 to 1866, the number of deaths from colliery accidents averaged 1000 per annum; and though in the next ten years the death rate decreased, it never fell under 800 a year.

---

[1] See also COAL, vol vi. p. 47.

[2] Compare with this the table at vol. vi. p. 74.

Exports of coals.

The production of coal in the United Kingdom was more than doubled in the period from 1855 to 1876, but the exports to foreign countries during the same time increased nearly eight-fold. From 4,976,902 tons in 1855 the exports rose to 9,170,477 tons in 1865, and to 11,702,649 tons in 1870. They further rose to 13,198,494 tons in 1872, to 13,927,205 tons in 1874, to 14,544,916 tons in 1875, and to 16,299,077 tons in 1876. Of the total exports of the year 1876, France took 3,160,555 tons, Germany 2,243,722 tons, and Italy, Russia, and Sweden and Norway each a little over a million tons, the remainder being distributed over thirty other foreign countries and British colonies. Vast as has been the amount of the coal exports in recent years, they still represent less than one-eighth of the coal produce of the country. The mines of the district of South Durham alone produced in 1876 considerably more coal than was exported to all foreign countries.

Iron ore.

Iron Ore.—Though vastly inferior, as a source of national wealth, to coal, and deriving nearly all its value from it, still the second most important produce of English mines, the iron ore, has the greatest effect upon the industrial character of the country. England and Wales alone produce iron ore, the amount raised in Scotland and Ireland being quite insignificant. It amounted in Scotland to 5226 tons, valued at £3432, and in Ireland to 116,066 tons, valued at £60,748, in 1876. The whole of the rest of the produce of the United Kingdom, 16,720,291 tons, valued at £6,761,525, was raised in England and Wales.

The following table exhibits the quantities and value of the iron ore raised in the chief producing counties and districts of England and Wales in the year 1876:—

Produce of Iron Ore in English and Welsh Counties.

Counties.	Quantities.		Value.		
	Tons.	Cwts.	£	s.	d.
Cornwall	18,390	0	10,566	18	0
Devonshire	9,936	10	5,075	15	0
Somersetshire	44,299	3	31,110	3	6
Gloucestershire	115,098	3	77,394	3	0
Wiltshire	83,957	0	20,989	5	0
Oxfordshire	26,140	0	5,228	0	0
Northamptonshire	1,161,130	10	173,366	10	0
Lincolnshire	573,374	15	101,622	19	0
Staffordshire, North	19,998	13	14,658	10	0
Lancashire	984,460	18	728,505	15	0
Cumberland	1,353,910	9	996,046	2	6

Northumberland and Durham	24,202	12	14,521	16	0
South Wales and Monmouthshire.	83,969	15	41,484	17	0
Iron Ore worked under the Coal Mines Regulation Act in other counties	5,659,423	0	3,378,933	6	0
Total, England and Wales	16,720,291	0	6,761,525	0	0

Manufacture of iron by charcoal.

Iron ore lies widely distributed all over England and Wales, and though at present mainly raised in the northern and western counties, and all the districts which contain coal, the union with which alone gives it industrial value, the geological strata containing it are equally to be found in the south and elsewhere. The earliest use of the iron ore in England, before the important discovery of the manufacture of pig iron by coal was known, was almost exclusively in the southern counties, more particularly in Sussex. "I have heard," says John Norden, the topographer, in his *Survey of Middlesex*, published in the latter part of the 17th century, "that there are, or recently were, in Sussex neere 140 hammers and furnaces for iron." William Camden, writing about the same time, adds that Sussex "is full of iron mines in sundry places, where, for the making and founding thereof, there be furnaces on every side, and a huge deal of wood is yearly burnt." Other writers refer to the burning of "cole," that is, charcoal, in the iron manufacture of the south of England.

Discovery of iron smelting by "pit coal."

The old iron manufacture came to an end towards the middle of the 18th century, with the destruction of the once plentiful woods and forests of England. However, the production of iron in the country was still estimated in 1740 at 17,350 tons, made in 59 "hammers and furnaces," being less than half the number mentioned by John Norden as existing in Sussex. Within the next few years the trade sank still lower, and was on the point of being extinguished, when at last the efforts of a number of enterprising men to make use of "pit coal" for making iron were crowned with success. Like most discoveries, this great one, destined to give a new course to the industrial and commercial history of England, was not the work of one man, but resulted from the labors of many; still an important share of it fell to the Darbys, father and son, the first of whom established, in 1709, with the help of skilled Dutch workmen, the celebrated Colebrookdale iron-works, in Shropshire. The father did not reap the benefits of his great enterprise, but the son was fully rewarded. He sat "watching the filling of his furnace for six days and nights uninterruptedly, and was falling into a deep sleep, when he saw the molten iron running forth." In December, 1756, the Colebrookdale iron-works were "at the top pinnacle of prosperity, making twenty or twenty-two tons per week, and sold off as fast as made, at profit enough."

Production of pig iron from 1756 to 1854.

At the date here given, the total production of pig iron in England was probably about 225,000 tons a year, but from that time it rose with extraordinary rapidity. It is estimated that 68,300 tons were produced in the United Kingdom in 1788, which amount had increased to 125,079 tons in 1796, and to 258,206 tons in 1806, a doubling in ten years. The production had again doubled in 1825, when it was 581,000 tons; and once more in 1839, in which year it had risen to 1,240,000 tons. In 1848, the total amount of pig iron produced was estimated to be over two millions of tons; and in 1854, the first year for which trustworthy statistics were gathered by the mining record office, the production surpassed three millions.

Production of pig iron, 1854 to 1876.

The following table exhibits the quantities and value of pig iron produced in the United Kingdom in every third year from 1855 to 1776:—

Years.	Quantities.	Value.
	Tons.	£
1855	3,218,154	8,045,385
1858	3,456,064	8,640,160
1861	3,712,390	9,280,975
1864	4,767,951	11,919,877
1867	4,761,023	11,902,557
1870	5,963,515	14,908,787
1873	6,566,451	18,057,739
1876	6,555,997	16,062,192

The pig iron produced in the United Kingdom in the year 1876 came from 17,813,818 tons of iron, of which amount 16,841,583 tons were raised at home, and the remainder, 972,235 tons, imported from foreign countries, principally from Italy, Spain, and Portugal.

Pig iron and coal consumption.

The following statement shows the amount of pig iron produced, and the quantity of coal used in its manufacture, in each of the divisions of Great Britain in the year 1876:—

	Pig Iron.	Coal.
	Tons.	Tons.
England	4,664,153	10,871,706
Wales	788,844	1,676,675
Scotland	1,103,000	3,050,000
Total Great Britain	6,555,997	15,598,381

It will be seen that the quantity of coal used in the manufacture of pig iron represented nearly one-eighth of the total coal produce of the year 1876.

Iron furnaces in England and Wales.

The following table exhibits the number of furnaces in blast, and the quantities of pig iron made, in the various counties of England and Wales, in the year 1876:—

Counties.	Furnaces in Blast.	Pig Iron made.
ENGLAND.	Number.	Tons.
Northumberland	1	823,172
Durham	50½	
Yorkshire, North Riding	75	1,261,013
Do. West Riding	34	235,451
Derbyshire	35	300,719
Lancashire	30	552,984
Cumberland	27	436,887
Shropshire	16	106,711
North Staffordshire	25	213,569
South do.	65	465,946
Northamptonshire	11	84,916
Lincolnshire	16	125,198
Gloucestershire	5	28,108
Wiltshire	2	29,479
Hampshire	...	
Somersetshire	1	
Total for England	393½	4,664,153
NORTH WALES.		
Denbighshire	3	32,723
Flintshire	1	
SOUTH WALES.		
Anthracite furnaces	6	20,421
Glamorganshire	28	321,754
Monmouthshire	35	413,946
Total for Wales	73	788,844
England and Wales	466½	5,452,997

State of iron manufacture.

The iron manufacture was not in a prosperous condition in the year 1876. The total number of existing furnaces in England and Wales was 771, so that more than 200 were standing idle. The total number of existing furnaces in England was 626, and in Wales 145, showing that the depression of trade was greatest in Wales, exactly one-half of the furnaces standing idle. The total number of active iron-works amounted to 159 in England, and 24 in Wales, at the end of 1876.

Production of lead.

Lead.—In comparison with coal and iron, all the other mineral products of the country are of small importance. Of these minor products, the highest on the list, as to value, is lead ore, raised in the United Kingdom to the value of £1,218,078 in 1876, and producing lead valued at £1,270,415. The quantities of lead ore raised in the year amounted to 79,096 tons, and the metallic produce to 58,667 tons. Of this total, 73,361 tons of ore were raised in England and Wales, producing 54,363 tons of lead. More than one-half of the lead ore and lead produced in England came from the counties of Durham and Northumberland, while two-thirds of the produce of Wales came from Montgomeryshire and Cardiganshire. There were altogether 392 lead mines in the United Kingdom in 1876, and of this number 287 were in England and Wales. The mines were very unequal in extent and produce. Derbyshire contained 140 lead mines, producing 2441 tons of ore and 2149 tons of metal; while Durham and Northumberland produced 23,285 tons of ore and 16,730 tons of metal in 28 mines.

Decline of lead produce.

The produce of the lead mines, after remaining stationary for many years, declined considerably from 1870 to 1876. In the fifteen years from 1854 to 1868 the average annual produce in the United Kingdom amounted to about 68,000 tons, valued at £1,400,000. The culminating point of production was reached in the year 1870, with 73,420 tons, valued at £1,452,715, after which there was a steady falling off, down to the amount of 1876. The decrease in the home produce of lead was accompanied by an increase in the imports of the metal, which amounted to 61,987 tons, valued at £1,411,988, in 1874, and rose to 79,825 tons, valued at £1,801,962, in 1875, and to 80,649 tons, valued at £1,749,978, in 1876. It will be seen that the imports of lead are considerably larger than the home production.

Production of tin.

Tin.—Next to lead in value, among the minor ores and metals, stands tin. In 1876 there were raised 13,688 tons of tin ore, producing 8500 tons of metallic tin, valued at £675,750. Tin ore is found nowhere but in Cornwall and Devonshire, the famous mines of Cornwall, which attracted foreigners thousands of years ago, producing the greater part. At the end of 1876 there were returned as existing in England 135 tin mines, of which number 104 were in Cornwall and 16 in Devonshire, the remainder consisting not of "mines," in the ordinary sense, but, more strictly, of "finding-places," situated on rivers and near the shore. The number and produce of tin mines have suffered a great decrease in recent years. In 1872 there were raised 14,266 tons of ore, producing 9560 tons of metal, valued at £1,459,990; in 1873, only 1,056,835 tons were raised, producing 9972 tons of metal, valued at £1,329,766, and in 1874 but 788,310 tons of ore, producing 9942 tons of metal, valued at £1,077,712. The year 1875 showed a further falling off to 735,606 tons of ore, with 9614 tons of metal, valued at £866,266, upon which followed the first-mentioned still lower production of the year 1876. During the same period, the imports of tin, in blocks and ingots, from foreign countries gradually increased. They amounted to 166,840 cwts., valued at £1,154,578, in 1872, and rose to 304,551 cwts., valued at £1,148,542, in 1876. It will be seen that while the total quantity of tin imported within the quinquennial period underwent a considerable increase, the total value not only did not augment, but actually decreased. The decline in price was probably one of the main causes of the decline in the production of tin.

Produce of copper.

Copper.—Next to tin in value, among the minor ores and metals, stands copper. The total product of copper ore raised in the United Kingdom in 1876 was 79,252 tons, of which, 71,756 tons were the produce of England and Wales, while 680 tons came from Scotland, and 6816 tons from Ireland. The total amount of the metal produced from the ores was 4694 tons, valued at £392,300, of which 4222 tons were made in England and Wales, 33 in Scotland, and 449 in Ireland. There were at the end of 1876 copper mines to the number of 101 in the United Kingdom,—England and Wales possessing 93, Scotland 1, and Ireland 7. Only the copper mines of England, and more particularly those of Cornwall and Devonshire, are of any importance. At the end of 1876 there was one copper mine in each of the counties of Cumberland, Cheshire, and Lancashire, 15 in Devonshire, and 65 in Cornwall, the latter producing 43,016 tons of ore and 3034 tons of metal. Even more than lead and tin, the production of copper has been greatly declining in recent years. In 1855 the total produce of copper was as high as 21,294 tons, valued at £3,042,877; which amount had fallen to 15,968 tons, valued at £1,706,261, in 1860. In 1865 the quantity had fallen to 11,888 tons, valued at £1,134,664; and in 1870 it had further declined to 7175 tons, valued at £551,309. Thus the decline continued, with slight fluctuations, till the production had reached the small amount of 1876. As with lead and tin, the copper imports grew largely while the production declined.

Produce of zinc.

Zinc.—The remaining metallic ores—zinc, silver, and gold—are but of trifling value. Zinc is found in five counties of England and seven of Wales, which together possess 53 mines. There are 3 more mines in the Isle of Man, and 1 in Scotland. In 1876, the total of zinc ore raised was 23,613 tons, producing 6641 tons of zinc, valued at £158,011. The production of zinc trebled in quantity and value in the sixteen years from 1852 to 1876. It amounted only to 2151 tons, valued at £50,548, in 1862, and in 1872 had risen to 5191 tons, valued at £118,076. The increase in production did not prevent a simultaneous increase in imports, which more than doubled in the decennial period from 1866 to 1876, amounting in the latter year to 29,327 tons, valued at £662,190, being more than four times the amount of the home produce.

Produce of silver and gold.

Silver and Gold.—Silver and gold, the so-called precious metals—though iron is infinitely more valuable under every point of view—form but imperceptible additions to the mineral wealth of the country. Of silver, always found in combination with lead ores, 483,422 ounces, valued at £106,222, were raised in the year 1876 in the United Kingdom, and of gold, 293 ounces, valued at £1138. There were, according to the returns of the mining record office, two "gold mines" in the United Kingdom, the one in Merionethshire, and the other in the county of Wicklow, Ireland. The former, situated at Clogan, produced 288 ounces, valued at £1119, in

1876. As for the Irish "gold mine," its yield was just 4 ounces, worth £18. The returns do not state the sum expended in raising the 4 ounces of Irish gold.

Produce of salt and clays.

Salt and Clays.—The sum total of England's mineral riches is completed by a variety of miscellaneous substances raised from the earth, such as salt, clays—including porcelain, potter's clay, and fire-clay—coprolites, oil shales, barytes, and gypsum. None of these are of much importance except salt and clays. The centre of the salt production is in Cheshire, at Northwich, Middlewich, Winsford, and other places; but there are also salt mines in Staffordshire and Worcestershire. In 1876 the total quantity of salt raised amounted to 2,273,256 tons, valued at £1,136,628, of which 854,538 tons, valued at £529,547, were exported to foreign countries, chiefly to the United States and British India. Of clays of all kinds, the total produce in 1876 was 3,971,123 tons, valued at £744,224. The finest of the clays, known as kaolin, or porcelain clay, is the produce of Cornwall and Devonshire, the former county raising 105,275 tons, and the latter 25,000 tons, in 1876. Of importance next to it, as potter's material, is the "Poole clay" of Dorsetshire, of which 72,105 tons were produced in 1876. Raised in much larger quantities than both the kaolin and the "Poole" are the fire-clays, the production of which in the year 1876 amounted to 1,514,902 tons. The fire-clays are found chiefly in the north and west of England and in South Wales. There were 171 fire-clay pits at the end of 1876, the largest number of them, 45, in Northumberland and Durham, and the next largest, 33, in South Wales.

Number engaged in mining operations.

Miners.—In the census returns of 1871 there were 376,783 persons distinguished as "miners," the number comprising 371,105 males and 5678 females. At the preceding census of 1861 there were 330,446 persons enumerated as "miners," of whom 330,352 were males and only 94 females. Thus there was a total increase of 46,337 persons so designated, comprising 40,753 males and 5584 females, in the ten years from 1861 to 1871. There were besides enumerated as "workers in stone and clay," 152,673 at the census of 1871, comprising 149,567 males and 3106 females. At the census of 1861 the total number of persons so classified was 144,773, so that there was an increase of 7900 persons in the decennial period.

V. *Textile Manufactures.*[1]—*Fisheries.*

Origin of the cotton manufacture.

There were two agencies, one moral and the other material, that gained for England its comparatively modern superiority in manufactures. Long after textile and other industries had been flourishing in the leading states of the Continent,—the Netherlands, Flanders, and France,—England remained a purely agricultural and pastoral country, content to export her riches in wool, and to import them again, greatly enhanced in value, as clothing. Thus it remained till religious persecution drove the flower of the industrial population of the West of Europe away from the homes of their birth; and, happy to find an asylum here, they liberally repaid English hospitality by establishing their own arts in the country, and teaching them to the inhabitants. Thus religious liberty formed the noble foundation of England's industrial greatness. Then came the material agent, machinery propelled by steam. The invention of the steam engine, following quickly upon that of the carding machine, the spinning jenny, and other ingenious machinery employed in textile manufactures, gave an extraordinary impulse to their development, and, with them, that of kindred branches of industry. At the basis of all of them was England's wealth in coal.

Inventions for spinning cotton.

Cotton Manufacture.—That England, not possessing the raw material, became the seat of the cotton manufacture, was owing, in the first instance, to the ingenuity of her inventors of machinery. Established as early as the beginning of the 17th century at Manchester, the cotton manufacture made no progress for a long time, and generation after generation clothed themselves in cotton goods spun by Dutch and German weavers. It was not till the latter part of the 18th century, when a series of inventions, unparalleled in the annals of industry, followed each other in quick succession, that the cotton manufacture took real root in the country, gradually eclipsing that of other European nations. But though the superior excellence of their machinery enabled Englishmen to start in the race of competition, it was the discovery of the new motive power, drawn from coal, which made them win the race. In 1815 the total quantity of raw cotton imported into the United Kingdom was not more than 99 millions of pounds, which amount had increased to 152 millions of pounds in 1820, and rose further to 229 millions in 1825, so that there was considerably more than a doubling of the imports in ten years. In 1830 the imports of raw cotton had further risen to 264 millions of pounds, in 1835 to 364 millions, and in 1840 to 592 millions of pounds.

Imports of raw cotton, 1841 to 1876.

The following table shows the progress, with fluctuations, of the cotton trade, in the annual imports, the exports, and the excess of imports of raw cotton during each, for every fifth year from 1841 to 1876:—

Years.	Total imports of raw Cotton.	Total exports of raw Cotton.	Excess of imports.
	℔	℔	℔
1841	487,992,355	37,673,585	450,318,770
1846	467,856,274	65,930,732	401,925,542
1851	757,379,749	111,980,394	645,399,355
1856	1,023,886,304	146,660,864	877,225,440
1861	1,256,984,736	298,287,920	958,696,816
1866	1,377,514,096	388,981,936	988,532,160
1871	1,778,139,776	362,075,616	1,416,064,160
1876	1,487,858,848	203,305,872	1,284,552,976

Number of cotton factories.

There were 2655 cotton factories in the United Kingdom at the end of 1874. They had 41,881,789 spindles and 463,118 power looms, and gave employment to 479,515 persons, of whom 187,620 were males and 291,895 females. The following statement gives the number of cotton factories in England—there are none in Wales—distinguishing those devoted to spinning and to weaving, and the total—including those both spinning and weaving, and all others—at various periods, from 1850 to 1874:—

Years.	Number of Factories.		Total number of Cotton Factories.
	Spinning.	Weaving.	
1850	762	229	1,753
1856	910	419	2,046
1861	1,079	722	2,715
1868	1,041	632	2,405
1870	1,085	649	2,371
1874	1,172	600	2,542

Number of spindles.

The following table shows the number of spindles used in the cotton factories of England, distinguishing those for spinning and for doubling—the total including all others—at various annual periods from 1850 to 1874:—

Years.	Number of Spindles.		Total Number of Spindles.
	Spinning.	Doubling.	
1850	8,685,392	10,055,410	19,173,969
1856	15,260,777	10,557,799	25,818,576
1861	15,077,299	13,274,346	28,351,925
1868	14,827,226	15,651,002	30,478,228
1870	17,302,982	15,309,505	32,613,631
1874	21,449,102	14,585,130	36,034,232

Number of power looms.

The subjoined table exhibits the number of power looms used in the cotton factories of England, both weaving and spinning, and weaving, at various annual periods from 1850 to 1874:—

Years.	Weaving.	Spinning and Weaving.	Total number of Power Looms.
1850	36,544	184,816	223,626
1856	65,880	209,609	275,590
1861	131,554	235,268	368,125
1868	137,892	206,827	344,719
1870	175,432	235,904	411,336
1874	170,665	260,724	431,389

---

[1] See also the separate articles on the different textile manufactures.

The following table gives the number of persons, male and female, employed in the cotton factories of England at various periods from 1850 to 1874:—

Number of Workers in Cotton Factories.

Year.	Males.	Females.	Total.
1850	131,610	160,052	291,662
1856	148,354	192,816	341,170
1861	173,704	233,894	407,598
1868	152,656	204,396	357,052
1870	171,793	243,177	414,970
1874	180,607	259,729	440,336

Of the males employed in 1874 there were 33,342 under thirteen years of age, and 37,016 from thirteen to eighteen years of age,—the rest, 110,249, being above eighteen years. Of the 259,729 females employed in cotton factories in 1874 there were 32,637 under thirteen years of age.

The cotton factories were distributed as follows over England at the end of 1874:—

Distribution of Cotton Factories over England.

Counties.	Number of Factories.	Number of Power Looms.	Number of Persons employed.
Middlesex, Surrey, and Kent......	18	18	397
Gloucester, Hereford, Salop, Stafford, Worcester, and Warwick..........................	19	3,000	5,278
Leicester, Rutland, Lincoln, and Notts........................	43	41	4,632
Cheshire....................................	184	29,948	36,485
Lancashire................................	1,911	373,061	352,003
Derbyshire................................	72	7,608	10,091
Yorkshire..............................	278	15,147	28,669
Durham, Northumberland, Cumberland, and Westmoreland................................	14	2,382	2,478
Essex, Suffolk, and Norfolk......	3	184	303
Total	2,542	431,389	440,336

It will be seen that Lancashire absorbs more than three-fourths of the manufacture of cotton fabrics in England.

Number of woollen factories.

Woollen and Worsted.—Second only to the cotton trade as a national industry is the manufacture of woollen and worsted textile fabrics. There were in 1874 in the United Kingdom 1800 woollen and 692 worsted factories. In the woollen factories there were in use 3,323,881 spindles and 57,090 power-looms, and they employed 134,605 persons; while in the worsted factories there were in use 2,382,450 spindles and 81,747 power-looms, and they employed 142,097 persons. Unlike cotton, the raw material for woollen fabrics is mainly produced at home; still for many years past the native supply has been insufficient, which necessitated imports from foreign countries and British colonies, ever increasing in amount. During 1840–1876 the imports of wool rose from 49 to 390 millions of pounds.

Imports of wool.

The following table exhibits the imports of wool into the United Kingdom from foreign countries and British colonies, the amount of re-exports, and the net balance of imports, for every fifth year from 1841 to 1876:—

Years.	Total Imports of Wool.	Total Exports (Foreign and Colonial).	Net Imports.
	℔	℔	℔
1841	56,170,974	2,553,671	53,617,303
1846	65,255,462	3,011,980	62,243,482
1851	83,311,975	13,729,987	69,581,988
1856	116,211,392	26,679,793	89,531,599
1861	147,172,841	54,377,104	92,795,737
1866	239,358,689	66,573,488	172,785,201
1871	323,036,299	134,866,304	188,169,995
1876	390,055,759	173,020,372	217,035,387

Woollen factories in England and Wales.

Of the 1800 woollen factories in existence in the United Kingdom at the end of 1874, England and Wales had 480; and of the 692 worsted factories, England and Wales had 239. The following table shows the number of woollen factories in England and Wales, the number of spindles and of power looms in use, and the number of persons employed, at various annual periods from 1850 to 1874:—

Years.	Number of Woollen Factories.	Number of Spindles.	Number of Power Looms.	Number of Persons Employed.
1850	1,306	1,356,691	9,170	64,426
1856	1,410	1,499,949	13,726	69,130
1861	1,456	1,846,850	20,344	76,309
1868	1,420	4,222,916	42,571	101,938
1870	1,550	2,081,931	37,356	100,640
1874	1,483	2,604,610	45,025	105,371

The subjoined table gives similar details regarding the worsted factories in England and Wales:—

Worsted Factories in England and Wales.

Years.	Number of Worsted Factories.	Number of Spindles.	Number of Power Looms.	Number of Persons Employed.
1850	493	864,874	32,617	78,915
1856	508	1,298,326	38,809	86,690
1861	512	1,245,526	42,968	82,972
1868	687	2,149,024	71,556	128,410
1870	599	1,766,636	63,443	103,514
1874	648	2,128,890	75,591	131,830

The number of persons employed in the woollen factories of England and Wales in 1874 comprised 54,119 males and 51,252 females. Of the males, 4391 were under thirteen years of age, 10,726 from thirteen to eighteen years of age, and 93,002 above eighteen. Of the females, 2841 were under thirteen, and 48,411 over thirteen years of age. In the worsted factories, the persons employed in 1874 comprised 53,995 males and 77,835 females. Of the males, 14,074 were under thirteen, 10,694 were from thirteen to eighteen, and 29,227 above eighteen years of age. Of the females, 15,394 were under thirteen, and 62,441 over thirteen years of age. It will be seen that the number of children, of both sexes, is far greater comparatively in the worsted than in the woollen factories.

Distribution of woollen factories.

The following table exhibits the distribution of the woollen factories over England and Wales, giving the number in different counties, with power looms and persons employed, at the end of 1874:—

Counties.	Number of Factories.	Number of Power Looms.	Number of Persons employed.
Herts, Bucks, Oxford, Northampton, Hants, Bedford, and Cambridge......................	10	231	984
Wilts, Dorset, Devon, Cornwall, and Somerset	69	2,586	7,695
Gloucester, Hereford, Salop, Stafford, Worcester, and Warwick..........................	36	1,226	4,978

Derbyshire......	1	84	125
Total	648	75,591	131,830

The preceding tables show that the chief seat of the woollen and worsted manufacture is in Yorkshire, while Lancashire stands second, but a long way behind. In the western and some of the midland counties where the trade is carried on, it is on a very reduced scale, as the factories have no power looms. The eastern counties likewise have at present but a very small share of the trade, which is now all but extinct in Norwich, the most ancient manufacturing town in the kingdom, where a colony of Flemings settled in the reign of Henry I., getting the long wool spun at the neighboring market-town of Worstead, after which the new produce was named. The once famous market-town itself has sunk to an obscure village.

Number of silk factories.

Silk.—Compared with the manufacture of goods made from cotton and wool, that of other textile fabrics is comparatively unimportant, the main articles being silk, flax, and hemp. As far as the United Kingdom is concerned, the manufacture of flax stands first among these minor textile fabrics; but taking England alone, the chief of them is silk. There were in 1874 in the United Kingdom 818 silk factories, with 1,336,411 spindles and 10,002 power looms, employing 45,559 persons. Of this total, only 4 factories, with 226 power looms, employing 740 persons, were in Scotland; and but 2 factories, with 7 power looms, employing 400 persons, were in Ireland.

Silk factories in England.

The following table shows the number of silk factories in England, with the number of spindles and power looms in use, and the number of persons employed, at various periods from 1850 to 1874:—

Years.	Number of Silk Factories.	Number of Spindles.	Number of Power Looms.	Number of Persons Employed.
1850	272	1,188,908	6,092	41,703
1856	454	1,063,555	9,260	55,300
1861	761	1,305,910	10,635	51,191
1868	587	968,182	14,511	39,956
1870	692	929,157	12,135	47,311
1874	812	1,103,893	9,759	44,419

The number of persons employed in the silk factories of England in 1874 comprised 12,772 males and 31,647 females. Of the males, 2324 were under thirteen, 2375 from thirteen to eighteen, and 8073 over eighteen years of age. Of the females, 4521 were under thirteen. The employment of children of both sexes in silk factories was on the decrease from 1850 to 1874, while during the same period it was largely on the increase in cotton factories, and also, but to a smaller degree, in the woollen and worsted manufacture.

The following table shows the distribution of silk factories over the various counties of England—there are none in Wales—with the number of power looms in use and of persons employed, at the end of the year 1874:—

Distribution of Silk Factories over England.

Counties.	Number of Silk Factories.	Number of Power Looms.	Number of Persons Employed.
Middlesex, Surrey, and Kent..	10	52	297
Herts, Bucks, Oxford, Northampton, Hunts, Beds, and Cambridge....................	6	......	1,162
Essex, Suffolk, and Norfolk....	19	2,109	5,815
Wilts, Dorset, Devon, Cornwall, Somerset, and Hants.	20	449	2,940
Gloucester, Hereford, Salop, Stafford, Worcester, and Warwick	518	1,876	7,909
Leicester, Rutland, Lincoln, and Notts......................	16	74	911
Cheshire.........	147	1,735	11,841
Lancashire..........................	24	2,666	5,376
Derbyshire	22	48	2,479
Yorkshire..........................	30	750	5,689
Total..........................	812	9,759	44,419

It will be seen from the above table that the silk manufacture is more dispersed over England than either that of cotton or woollen fabrics. The tendency to use machinery appears most pronounced in Lancashire and the three eastern counties, in both of which districts the number of power looms is nearly half as large as that of hands employed; while in other counties the number of power looms is very small in proportion to that of workers.

Number of flax factories.

Linen.—Next to silk in importance, as one of the minor textile manufactures of England, stands flax. At the end of 1874, there were in the whole of the United Kingdom 449 factories for spinning flax, using 1,473,800 spindles and 41,980 power looms, and employing 128,459 hands. In the returns for 1874, Scotland took the first rank as regards the number of flax factories, Ireland the second, and England the third rank. There were in Scotland at that date 159 factories, with 275,119 spindles and 18,529 power looms, employing 45,816 persons; and in Ireland 149 factories, with 906,946 spindles and 17,827 power looms, employing 60,316 hands.

Flax factories in England.

The following table gives the number of factories for spinning flax in England, with the number of spindles and of power looms in use, and the number of persons employed, at various annual periods from 1851 to 1874:—

Years.	Number of Flax Factories.	Number of Spindles.	Number of Power Looms.	Number of Persons Employed.
1851	135	265,568	1,083	19,001
1856	138	441,759	1,987	19,787
1861	136	344,308	2,160	20,305
1868	128	437,623	5,086	21,859
1870	155	269,768	3,048	19,816
1874	141	291,735	5,624	22,327

The number of persons employed in the flax-spinning factories of England in 1874 comprised 6856 males and 15,471 females. Of the males, 844 were boys under thirteen, 1380 lads from thirteen to eighteen, and 4632 men over eighteen years of age. Of the females, 1245 were children under thirteen, and 14,226 women over thirteen years of age. There was a slight increase in the proportion of children of both sexes employed in the flax factories of England in the period from 1850 to 1874. In the Scottish flax factories, during the same time, the increase of children, notably females, was very great. There were only 218 girls under thirteen employed in all the flax-spinning factories of Scotland in 1850, and the number had risen to 1956 in 1874.

Distribution of flax factories.

The chief seat of the flax manufacture is in Yorkshire. It is a new branch of industry in Leicestershire and the adjoining midland counties, where it did not exist previous to 1870.

The following table shows the distribution of flax factories over the various counties of England—there are none in Wales—at the end of 1874:—

Counties.	Number of Flax Factories.	Number of Power Looms.	Number of Persons Employed.
Middlesex, Surrey, and Kent..	3	8	164
Sussex, Hants, and Berks......	2	36	153
Essex, Suffolk, and Norfolk....	5	149	256
Wilts, Dorset, Devon, Cornwall, and Somerset.........	30	392	2,736
Gloucester, Hereford, Salop, Stafford, Worcester, and Warwick......................	5	99	960
Leicester, Rutland, Lincoln, and Notts....................	2	......	217
Lancashire........................	18	1,133	4,404
Derbyshire........................	2	95	17
Yorkshire..........................	59	3,507	12,058
Durham, Northumberland, Cumberland, and Westmoreland........................	14	149	1,174
Cheshire..........................	1	56	35
Total........................	141	5,624	22,327

Hemp and jute factories.

Hemp and Jute.—Among the minor textile manufactures, hemp and jute come next to flax. The hemp manufacture is of comparatively recent date. There were but five hemp factories in the United Kingdom in 1861, but they had increased to 61 in 1874. Of these 45 were in England, 12 in Scotland, and 4 in Ireland. The English hemp factories, situated mainly in Lancashire and the northern counties, had in use 6448 spindles and 22 power looms in 1874, and gave employment to 3039 persons, of whom 1574, or about one-half, were women. Of jute factories, there were in the United Kingdom 110 in 1874, England having 15, Scotland 84, and Ireland 11. The English jute factories, distributed over the northern and midland counties, had in use 21,754 spindles and 927 power looms in 1874, and employed 4933 persons, of whom 3423, or nearly three-fourths, were women. In 1861 the whole of the jute factories of England employed only 107 persons.

Hosiery, lace, and shoddy factories.

Hosiery, Lace, and Shoddy.—There are enumerated in parliamentary papers, and various official returns, a number of other existing factories, among them of hosiery, lace, "shoddy," hair, felt, and elastic fabrics. The hosiery factories of the United Kingdom employed 11,980, and the lace factories 10,373 persons in 1874; but all the others gave employment, in the aggregate, to less than 9000 workers. The hosiery factories were all in England, with the exception of 4 in Scotland, employing 1006 persons. In the English hosiery factories, 65 in number, nearly all in Leicestershire and adjoining midland counties, there were 10,914 persons employed in 1874, about one-half of them women. The hosiery factories of England more than doubled from 1861, when their number was 65, to 1874. The same was the case with the lace factories, which increased from 186 in 1868 to 311 in 1874. Another notable textile industry enumerated in the official returns is that of "shoddy factories." There were of these establishments, 125 in the United Kingdom in 1874, all of them in England, with the exception of some very small Scottish ones, returned as employing together 7 persons. The English shoddy factories, dispersed in 1874 over Yorkshire and Lancashire, with but a few in other counties, had in use in that year 101,134 spindles and 1437 power looms, and employed 3424 persons, more than one-half of them women. There was an increase in the shoddy factories of Lancashire from 1868 to 1874, but a decrease during the same period in those of Yorkshire.

Supervision of factories.

Factory Supervision.—To protect the health of the people employed in English manufacturing industries, and to preserve them from accidents of all kinds, parliament passed in recent years a number of laws, known generally as the Factory Acts. In these Acts, the hours of labor are restricted, more especially for young persons and women, who cannot be set to work for more than 12 hours on any day, and not for more than 60 hours per week. The due execution of the Factory Acts is superintended by inspectors of factories, appointed by the Government, who have to make to the home secretary half-yearly reports, which are printed and laid before parliament. In a recent report it is stated that the laws passed are constantly more appreciated both by employers of labor and by the workers, but that the latter are subjected to much suffering through stagnation of trade. The latter is ascribed mainly to foreign competition. While there is doubtless truth in this view, there can be equally little doubt that other causes have affected, and continue to affect, English manufacturing industry.

Fisheries: number of boats.

FISHERIES.—The stagnation of trade which made itself felt, in recent years, in the chief manufactures, operated also upon the fisheries. It appears from official returns that there was a gradual decrease in the number of fishing boats, as will be seen from the subjoined table, which gives the number of boats of which the tonnage was known, for each division of the United Kingdom in the years 1872, 1873, and 1874:—

Divisions.	1872.	1873.	1874.
	Number.	Number.	Number.
England and Wales........	14,237	14,171	14,126
Scotland......................	14,451	13,954	13,471
Ireland........................	8,450	7,193	6.529
Isle of Man..................	375	371	377
Channel Islands............	783	600	568
Total..................	38,296	36,289	35,071

Tonnage of fishing boats.

The following table shows the tonnage of the preceding number of fishing boats, in each of the years named:—

Divisions.	1872.	1873.	1874.
	Tons.	Tons.	Tons.
England and Wales........	140,535	145,134	150,268
Scotland......................	92,595	92,224	91,119
Ireland........................	28,651	25,629	25,226
Isle of Man..................	5,047	5,032	5,185
Channel Islands............	2,988	2,725	2,469
Total..................	269,816	270,744	274,267

It will be seen that there was an increase, during the three years, in the total tonnage of the English, but a decrease in that of the Scottish and Irish fishing boats, as well as in that of the Channel Islands.

Classification of fishing boats.

The fishing boats of the United Kingdom are divided by the Board of Trade into three classes,—the first class comprising all boats over 15 tons; the second all boats under 15 tons, propelled otherwise than by oars; and the third class all boats navigated only by oars. The number of the first class in England and Wales at the end of 1874 was 2934, with a tonnage of 110,500, and in Scotland 2407, with a tonnage of 40,629. Of fishing boats of the second class there were at the same date 8313, with a tonnage of 35,670, in England, and 9815, with a tonnage of 48,124, in Scotland. Of boats of the third class, there were in England 2879, with a tonnage of 4098, and in Scotland 1249, with a tonnage of 2366. Thus England had the superiority in vessels of the first and third, but not in those of the second class. The fisheries of England are devoted mainly to the netting of mackerel, pilchards, and similar fish, and those of Scotland to cod, ling, and herrings.

Imports and exports of fish.

The imports of fish from foreign countries have in recent years been on the increase, and the exports on the decrease. The total value of the imports of fish in 1872 was £859,042, and in 1876 it amounted to £1,459,974. The total exports of fish were of the value of £1,183,801 in 1872, and of £624,726 in 1876. The exports are chiefly in herrings, of which 631,750 barrels were shipped to foreign countries in 1872, and 426,588 barrels in 1876. (See also FISHERIES.)

VI.—*Commerce.—Shipping.*

Progress of British commerce.

British commerce received an enormous development, unparalleled in the history of any nation, during the half a century from 1826 to 1876. In the year 1826 the aggregate value of the imports into and exports from the United Kingdom amounted to no more than £88,758,678; while the total rose to £110,559,538 in 1836, and to £205,625,831 in 1846. In 1856 the aggregate of imports and exports had risen to £311,764,507, in 1866 to £534,195,956, and in 1876 to

£631,931,305. Thus the commercial transactions of the United Kingdom—those of England, by itself, cannot be given—with foreign states and British colonies increased more than seven-fold in the course of fifty years.

Imports and exports, 1864 to 1876.

The two following tables exhibit the values of the annual imports, of the total annual exports of British home produce, and of the total imports and exports of the United Kingdom—the latter including exports of foreign and colonial produce—as well as the proportions per head of population, for every third year from 1864 to 1876:—

Years.	Total Imports.	Exports of British Home Produce.	Total Imports and Exports.
	£	£	£
1864	274,952,172	160,449,053	487,571,786
1867	275,183,137	180,961,923	500,985,666
1870	303,257,493	199,586,322	547.338,070
1873	371,287,372	255,164,603	682.292,137
1876	375,154,703	200,639,204	631,931,305

Years.	Imports.			Exports of British Produce.			Total Imports and Exports.		
	Proportion per Head of Population.			Proportion per Head of Population.			Proportion per Head of Population.		
	£	s.	d.	£	s.	d.	£	s.	d.
1864	9	5	7	5	8	4	16	9	0
1867	9	1	5	5	19	4	16	1	3
1870	9	14	4	6	7	11	17	10	10
1873	11	11	2	7	18	10	21	4	9
1876	11	6	8	6	1	3	19	1	11

Foreign import markets.

The following table exhibits the value of the imports into the United Kingdom from the principal British possessions and foreign countries in each of the years 1875 and 1876:—

Imports.	Year 1875.	Year 1876.
From British Possessions:—	£	£
India	30,137,295	30,025,024
Australasia	20,559.154	21,961,929
British North America	10,212,624	11,023,782
West Indies	5,414,059	6,894,331
Cape of Good Hope and Natal	4,478,960	4,192,416
Ceylon	4,380,821	3,134,183
Straits Settlements	3,149,310	2,641,946
Hong Kong	1,154,910	1,356,850
All other possessions	1,753,874	3,102,115
Total from British possessions	84,423,971	84,232,576
From Foreign Countries:—		
United States	69,590,854	75,899,008
France	46,720,101	45,304,854
Germany	21,836,401	21,115,189
Russia	20,708,901	17,574,488
Netherlands	14,836,648	16,602,154
China	13,607,582	14,938,641
Belgium	14,822,240	13,848.293
Egypt	10,895,043	11,481,519
Sweden and Norway	8,918,638	10,654,311
Spain	8,660,953	8,763,146
Turkey	6,555,714	7,444,323
Peru	4,884,181	5,630,670
Brazil	7,418,605	5,178,386
Denmark	4,241,671	4,217,934
Italy	4,632,619	4,152,201
Chili	4,196,096	3,584,598
Portugal	4,444,071	3,361,071
Spanish West Indies	3,668,776	2,943,385
Greece	1,762,301	1,799,377
Argentine Republic	1,359,783	1,664,029
Philippine Islands	1,559,500	1,442.556
Java and dependencies	1,442,607	1,440,860
Roumania	594,158	1,238,091
Uruguay	1,208,590	841,314
All other countries	10,306,440	9,701,729
Total from Foreign Countries	289,515,606	290.822.127
Total imports	373,939,577	375,154,703

Foreign export markets.

The exports of British home produce from the United Kingdom in each of the years 1875 and 1876 were sent to the following colonial possessions and foreign countries:—

Exports of Home Produce.	Year 1875.	Year 1876.
To British Possessions:—	£	£
India	24,246,406	22,405,420
Australasia	19,491,247	17,681,661
British North America	9,036,583	7,358,151
Cape and Natal	4,909,856	4,368,841
Hong Kong	3,599,811	3,080,376
West Indies	2,186,527	2,927,996
Straits Settlements	1,961,634	1,968,946
Gibraltar	969,222	1,120,965
Ceylon	1,076,752	1,073,505
All other possessions	2,116,721	2,873,363
Total to British Possessions	71,092,163	64,859,224
To Foreign Countries:—		
Germany	23,287,883	20,082,262
United States	21,868,279	16,833,517
France	15,357,127	16,085,615
Netherlands	13,118.691	11,777,192
Italy	6,766,698	6,689,402
Russia	8,059.524	6,182,838
Turkey	5,889,905	5.922,825
Brazil	6,869,491	5,919,758
Belgium	5,781,938	5,875,407
China	4,928,500	4,611,180
Sweden and Norway	4,538,455	4,224,719
Spain	3,430,340	3,992,365
Egypt	2,945,846	2,630,407
Portugal	2,563,067	2,231,191
Denmark	2,323,707	2,199,106
Japan	2,460,227	2,032,685
Spanish West Indies	2,630,634	2,015,113
Chili	2,207,418	1,945,791
Java	1,735,996	1,676,193
Argentine Confederation	2,386,002	1,543.532
Uruguay	713,830	1,006,307
Roumania	1,054.744	707,568
All other countries	2,738,877	9,595,007
Total to Foreign Countries	152,373,800	135,779,980
Total exports of home produce	223,465,963	200,639,204

Concentration of British commerce.

It will be seen from the preceding tables that the bulk of the commercial transactions of the United Kingdom, both as regards imports and exports, is with but a few states—mainly three British colonies and eight or nine foreign countries. In the same manner, the great mass of imports, as well as of exports of British produce centres, in each case, in about half a dozen principal articles. More than one-half of the total imports into the United Kingdom are made up of the six articles enumerated in the following table, one-half of which represent food for the nation, and the other half raw material for its manufactures. The table shows the value of each of these six articles imported into the United Kingdom during the years 1875 and 1876:—

Principal imports.

Principal Articles Imported.	1875.	1876.
	£	£
1. Corn and flour	53,086,691	51,812,438
2. Cotton, raw	46,259,822	40,180,880
3. Wool, sheep, and other	23,437,413	23,637,809
4. Sugar, raw and refined	21,548,303	20,456,977
5. Wood and timber	15,424,498	19,140,526
6. Tea	13,766,961	12,697,204

Increase of imports, and decrease of exports.

The most important fact in connection with the foreign commerce of the United Kingdom in recent years, is that there has been a gradual and steady increase of imports, together with a decrease of exports of home produce. The movement began in 1872. Up to that time, the exports of British home produce had kept on increasing with the imports, although at a lesser rate, and far inferior in aggregate value; but a change took place in the latter year. While the imports continued their upward course, gradually rising from £354,693,624 in 1872 to £375,154,703 in 1876, the exports of British produce fell from £256,257,347 in 1872 to £200,639,204 in 1876. The decline in exports, regular and steady throughout the period, and with a tendency to become more pronounced every year, affected all the principal articles of British home produce just enumerated. The value of the cotton manufactures exported sank from £80,164,155 in 1872 to £67,641,268 in 1876; woollen fabrics from £38,493,411 to £23,020,719; iron and steel from £35,996,167 to £20,737,410; coals from £10,442,321 to £8,904,463; machinery from £8,201,112 to £7,210,426; and linen manufactures from £10,956,761 to £7,070,149. The decline during the four years, it will be seen, was greatest of all in textile manufactures, and least in coals and machinery.

Principal exports of British produce.

The six principal articles of British produce exported to colonial possessions and foreign countries are derived from the labors of either manufacturing or mining industry. It may be gathered from the preceding chapters on mines and minerals, and on manufactures, to what an extent these six great export articles are the produce of each of the divisions of the United Kingdom.

Principal articles exported.	1875.	1876.
1. *Cotton manufactures:*	£	£
Piece goods, white or plain...	33,255,013	31,454,280
" printed or dyed.	19,900,918	18,494,492
" of other kinds...	5,442,922	4,910,763
Cotton yarn..........................	13,172,860	12,781,733
Total........................	71,771,713	67,641,268
2. *Woollens and worsted:*		
Cloths, coatings, etc.............	6,850,203	6,451,410
Flannels, blankets, and baizes	1,239,637	1,014,886
Worsted stuffs......................	11,159,914	9,141,605
Carpets and druggets..........	1,159,979	911,873
All other sorts.....................	1,249,592	1,083,704
Woollen and worsted yarn...	5,099,307	4,417,241
Total	26,758,632	23,020,719
3. *Iron and steel:*		
Iron, pig and puddled.........	3,449,916	2,842,434
" bar, angle, bolt and rod	2,725,907	1,945,445
" railroad, of all sorts.....	5,453,836	3,700,105
" wire	780,037	731,148
" tinned plates........	3,686,607	2,891,693
" hoops and plates.........	3,304,148	2,853,621
" wrought, of all sorts.....	4,342,492	4,041,418
" old, for re-manufacture	102,837	95,977
Steel, wrought and unwrought	1,901,491	1,635,569
Total	25,747,271	20,737,410
4. *Coals, cinders and fuel*	9,658,088	8,904,463
5. *Machinery*	9,058,647	7,210,426
6. *Linen:*		
White or plain	5,904,958	4,365,072
Printed, checked, or dyed.....	470,295	449,918
Of other sorts......................	897,667	805,646
Linen yarn.................	1,855,684	1,419,513
Total........................	9,128,604	7,070,149

Customs receipts of the United Kingdom.

Customs Receipts.—While the distribution of the exports from each of the three great divisions of the United Kingdom may be judged by their comparative manufacturing activity, that of the imports can be approximately ascertained—making due allowance for great centres of commerce—from the custom-house returns. The receipts of the customs were as follows in each of the years 1875 and 1876:—

	Year 1875.	Year 1876.
	£	£
England and Wales..................	15,763,666	15,802,004
Scotland..................................	1,597,863	1,667,915
Ireland	1,755,487	1,829,881
Total, United Kingdom.......	19,117,016	19,299,800

Customs receipts at the chief English ports.

More than one-half of the total customs receipts of the United Kingdom, and nearly two-thirds of those of England and Wales, are collected in London; while the amount collected at Liverpool is not very far from the total receipts of Scotland and Ireland. Besides London and Liverpool, there are but eight towns of England and Wales, out of eighty-seven, which have custom-house establishments, where the collection amounts to £100,000 and more per annum. The following is a list of these eight ports, together with London and Liverpool, giving the sums collected by the customs in each of them, in the years 1875 and 1876:—

Ports.	Year 1875.	Year 1876.
	£	£
London....................................	9,940,139	9,981,021
Liverpool	2,919,419	2,979,241
Bristol.....................................	691,730	673,395
Newcastle.............	334,738	304,422
Manchester................................	150,255	161,985
Hull	161,461	159,009
Exeter.......................................	128,334	128,809
Leeds	137,193	126,422
Chester	103,013	105,918
Sunderland	107,500	101,609

The table indicates commerce in goods only that pay duty; otherwise Liverpool would show larger returns.

Great centres of commerce.

It appears from the returns of the last thirty years that the commerce of the country has a constantly growing tendency towards concentration, and that while the customs receipts of the smaller ports are gradually decreasing, there is corresponding increase in those of the two chief ports, London and Liverpool, which are gradually becoming the all-absorbing centres of England's international trade and navigation.

Progress of shipping.

Shipping.—The shipping of the United Kingdom increased six-fold in the period from 1840 to 1876. In the year 1840 the total tonnage of vessels, British and foreign, which entered at ports of the United Kingdom was 4,657,795; and in the year 1850 it had risen to 7,100,476; while in 1860 the total tonnage was 12,172,785. The rise continued uninterrupted, as will be seen from the following table, which gives the tonnage of British and of foreign vessels which entered and cleared at ports of the United Kingdom every third year from 1864 to 1876:—

Years.	Entered.		
	British.	Foreign.	Total.
	Tons.	Tons.	Tons.
1864	9,028,100	4,486,911	13,515,011
1867	11,197,865	5,140,952	16,338,817
1870	12,380,390	5,732,974	18,113,364
1873	14,541,028	7,323,929	21,864,957
1876	16,511,951	8,555,313	25,067,264

Years.	Cleared.		
	British.	Foreign.	Total.
	Tons.	Tons.	Tons.
1864	9,173,575	4,515,923	13,689,498
1867	11,172,205	5,245,090	16.417,295
1870	12,691,790	5,835,028	18,526,818
1873	15,106,316	7,468,713	22,575,029
1876	16,930,028	8,787,610	25,717,638

The total tonnage here enumerated comprised both sailing vessels and steamers. The number and tonnage of the former is decreasing, and that of the latter increasing, to such an extent that steam vessels appear likely to absorb the whole international commerce of the country.

The following table of the principal ports of the country summarizes the tonnage of vessels *with cargoes* which entered and cleared coast-wise, and from and to foreign countries and British possessions, in 1876:—

Port.	Entered.	Cleared.	Total.
	Tons.	Tons.	Tons.
London..........................	9,074,519	4,503,673	13,578,192
Liverpool	6,380,217	5,587,416	11,967,633
Newcastle[1] and North and South Shields[1]....	1,481,874	5,168,330	6,650,204
Cardiff [1]........................	671,209	2,883,535	3,554,744
Hull	1,691,328	1,334,285	3,025,613
Sunderland[1]....................	303,820	2,289.710	2,593,530
Southampton	992,447	705,517	1,697,964
Bristol.......	1,087,602	496,679	1,584,281
Swansea[1]	567,741	992,092	1,559,833
Newport[1]........................	508,474	959,792	1,468,266
Hartlepool[1]	452,159	956,248	1,408,407

[1] These are almost exclusively mineral ports.

Tonnage of vessels on the register.

The subjoined table shows the total tonnage of the sailing vessels and steamers registered as belonging to the United Kingdom, at the end of each third year from 1864 to 1876:—

Years.	Sailing Vessels.	Steamers.	Total.
	Tons.	Tons.	Tons.
1864	4,930,219	697,281	5,627,500
1867	4,852,911	901,062	5,753,973
1870	4,577,855	1,112,934	5,690,789
1873	4,091,379	1,713,783	5,805,162
1876	4,257,986	2,005,347	6,263,333

Increase of steam navigation.

During the period 1864–76 the number and tonnage of sailing vessels registered as belonging to the United Kingdom decreased, but the steamers increased from 2490 to 4335, and the table shows that their tonnage nearly quadrupled. The latter fact indicates a doubling of the average tonnage of steamships, the wants of commerce requiring them to be more and more large. Nearly three-fourths of the total shipping of the United Kingdom belongs to England and Wales.

The total tonnage of the United Kingdom, far larger than that of any other country, represents by itself more than one-third of the shipping of all the maritime states of the world.

Ship-building.

Ship-building has long been an industry of great importance in England, although of late years it has suffered considerable fluctuations. The principal centres of the industry are the Thames, the Tees, the Tyne, and Sunderland on the east coast, and Liverpool, Barrow, and Whitehaven on the west. A very large proportion of vessels built in recent years are constructed of iron, with the consequence that the ship-building trade has mostly settled in those parts of the coast that are nearest to the iron and coal fields.

In 1874 the total amount of shipping built in England reached 277,984 tons; in 1875, 220,036 tons; and in 1876, 189,840 tons. In Scotland there were built 166,214 tons, and in Ireland 4311 tons in 1876. The numbers do not include ships built on foreign account.

VII. *Railways.—Canals and Roads.*

Influence of railways.

Far greater even than the impulse given to the country's foreign commerce by steam navigation has been the vast progress of internal communication effected by railways. The first ordinary roads deserving the name of highways were made in 1660, and canal building began in the middle of the following century; but though roads and canals aided materially in raising the commercial and industrial activity of the nation, their fostering agency was very slight compared with that of railways. In the half century during which England has built railways, its material progress has been vastly greater than that of the whole five previous centuries.

Early English railways.

The first line of railway on which carriages were propelled by steam engines, that from Stockton to Darlington, fourteen miles in length, was opened September 27, 1825. Although this little line, pioneer not only of England's, but the world's railways, proved a great success, it had no immediate successors of any note till five years after, when the first really important railway, connecting two great centres of commerce, was finished. This was the line from Manchester to Liverpool, opened September 15, 1830, when Mr. Huskisson was accidentally killed. As yet no railway had come near the metropolis, but great efforts were made by George Stephenson and his friends to get permission for constructing a line from London to Birmingham. The bill brought into parliament for this purpose met with the most violent opposition, chiefly on the part of the great land-owners, who, so far from seeing that the new mode of communication would immensely enhance the value of their properties, loudly proclaimed that the substitution of steam for horse-power would be "the curse and the ruin of England." It took three years to get the bill for the London-Birmingham railway, which was passed at last in the session of 1833, obtaining the royal assent on the 8th of May. The first sod of the great line was cut at Chalk Farm, London, on the 1st of June, 1834. Enormous engineering difficulties had to be overcome, originating not so much from the nature of the ground as from intense public prejudice against the new mode of locomotion. Instead of following the course of the old high-road, running along valleys, the line had to be pushed, by numerous viaducts and tunnels, over hollows and under hills, so as to avoid touching any considerable towns. It took five years to construct the railway from London to Birmingham, at a cost of over four millions. Even friends of the railway presaged that such outlay could not by any possibility be remunerative; but the contrary became evident from the moment the line was opened, in 1838. The first great "trunk" line proved a striking success, and its opening settled, without further controversy, the establishment of the new system of intercommunication in England.

The first great trunk line.

Origin of the leading railway companies.

All the great railway systems of England sprang into existence within less than ten years after the opening of the London-Birmingham line. Out of the latter grew, in the first instance, one of the largest of companies, the London and North-Western, while the most extensive system, as regards mileage, the Great Western, originated in a line from Paddington, London, to Bristol, for which an Act of Parliament was obtained in 1835, and which was opened in 1841. In 1836 a bill passed the legislature erecting the "Great North of England" Railway Company, from which was developed the now third largest of English railway systems, the North-Eastern. A few years subsequently various other Acts were passed, sanctioning the "Midland Counties" and the "North Midland" lines, from which sprang the present Midland system, fourth largest of English railway companies. The construction of railways, up to this time, was confined almost exclusively to England; the work was begun much later in Scotland, and still later in Ireland.

Growth of railways from 1825 to 1850.

The total length of railways in the United Kingdom at the end of the year 1825, which saw the opening of the first line, was 40 miles, constructed at a cost of £120,000. Five years later, at the end of 1830, there were not more than 95 miles, built at a cost of £840,925, but at the end of 1835 there were 293 miles, costing £5,648,531. Thus, in the first five years of railway construction, from 1825 to 1830, the mileage doubled; while in the second five years, from 1830 to 1835, it trebled. It quintupled in the next five-yearly period, till the end of 1840, when the total length of miles of railway in the kingdom had come to be 1435, built at a cost of £41,391,634, as represented by the paid-up capital of the various companies. The next five years saw again nearly another doubling of length of lines, for at the end of 1845 there were 2441 miles of railway, created by a paid-up capital of £88,481,376. Not far from a fresh trebling took place in the course of the next quinquennial period, and at the end of 1850 there were 6621 miles of railway, constructed at the cost of £240,270,745. Nearly all the railways opened up to this date were main or "trunk" lines, connecting more or less busy centres of population, the traffic between which was so large as to require double lines. Unlike most European countries up to the present time, England began railway building on a scale commensurate with the importance of the new mode of intercommunication, the leaders of the great enterprise foreseeing clearly the ultimate requirements of their work. It thus came to pass that double lines were made the rule, and single lines the exception. More recently, however, an increase has taken place in the construction of the latter, owing to the extension of short branches from the main lines.

Growth of railways from 1856 to 1876.

The length of railways open for traffic in the United Kingdom, either with double or single lines, and the amount of authorized capital, were as follows at the end of each fifth year from 1856 to 1876:—

Years.	Double or more lines.	Single lines.	Total.
	Miles.	Miles.	Miles.
1856	6,266	2,444	8,710
1861	6,893	3,972	10,865
1866	7,711	6,143	13,854
1871	8,338	7,038	15,376
1876	9,169	7,703	16,872

Years.	Authorized Capital.		
	Shares and Stock.	Loans and Debentures.	Total.
	£	£	£
1856	282,890,751	94,877,156	377,767,907
1861	322,369,654	107,503,292	429,872,946
1866	466,151,633	154,412,773	620,564,406
1871	451,898,908	163,827,982	615,726,890
1876	549,095,705	192,706,822	741,802,527

Distribution of railways over the United Kingdom.

Nearly three-fourths of the railways of the United Kingdom, and far more than three-fourths of the capital invested in them, fall to the share of England and Wales. The length of lines open for traffic in each of the three divisions of the kingdom, and the amount of authorized capital, were as follows on the 31st December, 1876:—

Distribution of Capital.

Division.	Double or more lines.	Single lines.	Total.	Shares and Stock.	By Loans and Debentures.	Total Authorized Capital
				£	£	£
England and Wales.......	7,591	4,398	11,989	449,973,593	161,438,942	611,412,535
Scotland	1,063	1,663	2,726	71,595,107	21,130,250	92,725,357
Ireland	515	1,642	2,157	27,527,005	10,137,630	37,664,635
United Kingdom..	9,169	7,703	16,872	549,095,705	192,706,822	741,802,527

Impulse to travelling given by railways.

Among the most marvellous effects produced by railways was the incentive given by them to the population to move from one place to another. Before the making of ordinary roads, that is, previous to the middle of the 17th century, and the old era of packhorses and bridle-paths, there was scarcely any movement worth the name; and the immense majority of people had to live and die in the places where they were born, simply through not being able to transport themselves elsewhere, even for a short distance. A change took place when highways came to be made, with stage-coaches rolling along them at a rate of from six to ten miles an hour. But the accommodation afforded by these new means of travelling was necessarily limited, besides being costly, in time as well as money, and the mass of the people could not avail themselves of it. But what was impossible for "the coach" was the easiest achievement for "the train" of coaches. In "the train," placed upon two longitudinal lines of iron rails, and propelled by steam, the whole nation for the first time obtained freedom of movement. The ancient packhorses carried their hundreds, and the stage-coaches their thousands; but the railways carried their millions—and more millions than ever stage-coaches carried thousands.

Passenger traffic of railways, 1832 to 1876.

The railways carried their first million of passengers in 1833, the year in which Stephenson won his great parliamentary battle in getting the bill for the London-Birmingham line passed. The number of passengers carried per mile in 1832 was 4860, but before other ten years were gone, the number of passengers had not only increased in proportion with the opening of new lines, but more than doubled per mile, and, instead of being under 5000, had in 1842 come to be near 12,000. The following table exhibits the growth of the passenger traffic on the railways of the United Kingdom, giving the length of lines open, the total number of passengers carried, and the number per mile, in every fifth year from 1846 to 1876:—

Years, Dec. 31.	Length of Lines open for Traffic.	Total Number of Passengers.	Number of Pasengers per Mile.
	Miles.		
1846	3,036	43,790,983	14,423
1851	6,890	85,391,095	12,309
1856	8,707	129,347,592	14,855
1861	10,869	173,773,218	15,988
1866	13,854	274,403,895	19,734
1871	15,376	375,406,146	24,415
1876	16,872	538,681,722	31,928

The table shows, more clearly than could be expressed by any description in words only, the striking changes effected by railways in the migratory habits of the people in the course of a generation. While the number of passengers was little above 14,000 per mile in 1846, it was nearly 32,000 in 1876. The number of passengers carried on the railways of the United Kingdom in the year 1876 was equal to four times the population of Europe, and more than half the estimated population of the globe.

Passenger traffic in 1876.

Considerably more than four-fifths of the passenger traffic on the railways of the United Kingdom is in England and Wales. The number of railway passengers in England and Wales, in Scotland, and in Ireland, and the numbers travelling by each class of railway, were as follows in the year 1876:—

Divisions.	1st Class Passeng'rs.	2d Class Passengers.	3d Class Passengers.	Total.
England and Wales......	38,302,841	58,949,892	383,686,658	480,939,391
Scotland	4,693,843	3,319,741	31,978,057	39,991,641
Ireland	1,862,382	4,208,562	11,285,319	17,356,263
United Kingdom..	44,859,066	66,478,195	426,950,034	538,287,295

Not included in the above summary are season-ticket holders, to the number of 394,427—345,656 in England and Wales, 26,481 in Scotland, and 22,290 in Ireland—the addition of which brings the total number of passengers to 538,681,722 in the year 1876.

The total receipts, the total working expenditure, and the net receipts of the railways in each division of the United Kingdom were as follows in the year 1876:—

Receipts and Expenditure of Railways.

Divisions.	Total Receipts.	Total Working Expenditure.	Net Receipts.	Proportion of Expenditure to Total Receipts.
	£	£	£	Per Cent.
England and Wales	52,476,319	28,466,366	24,009,953	54
Scotland	6,965,091	3,597,993	3,367,098	52
Ireland	2,774,365	1,471,150	1,303,215	53
United Kingdom..	62,215,775	33,535,509	28,680,266	54

Passenger and goods traffic.

The receipts of the railways of England and Wales in 1876 were derived to the extent of 55 per cent. from the goods traffic, and of 45 per cent. from passenger traffic. In 1854 the total receipts were exactly alike from the two sources, but after that year the proportion contributed by goods gradually rose, reaching 51 per cent. in 1858, 52 per cent. in 1862, 53 per cent. in 1863, 54 per cent. in 1867, and 55 per cent. in 1873. In Scotland the receipts from goods traffic in recent years amounted to 85 per cent. of the total; but in Ireland the passenger traffic furnished 53 per cent. of the total receipts.

Number of railway companies.

The construction of railways in England was undertaken originally by a vast number of small companies, each obtaining separate Acts of Parliament deemed requisite for their existence. But many years did not elapse before it was discovered that there could be neither harmonious nor profitable working of a great many systems, and this led to a series of amalgamations, by which the majority of the lines were brought under the management of a few great corporations. In the official "Railway Returns" issued by the Board of Trade, there were still 92 independent companies enumerated as existing in England and Wales at the end of 1876, but the mass of these consisted of very small undertakings. Virtually, the railways of the country were controlled by seven leading companies, as follows:—

Railway Companies.	Seat of Management.	Length of System Dec. 31, 1876.
		Miles.
Great Western	London	2,058
London and North-Western.....	London	1,632
North-Eastern.......................	York	1,429
Midland	Derby	1,238
Great Eastern...........	London	859
London and South-Western	London	687
Great Northern........	London	640

The seven great companies.

The seven great railway companies here enumerated—which might be reduced to six, the North-Eastern and Great Northern practically forming a united system—held between them 8543 miles on the 31st December, 1876, representing nearly all the main lines of the country. It seems probable that, with the exception, perhaps, of two or three companies south of the Thames, possessing, in the communication with the Continent, an independent traffic, all the others will gradually follow the process of absorption, more and more strongly developed in recent years. It may be that the process will ultimately reach its furthest solution by all the railways being placed by purchase, the same as the telegraphs, under the sole control of the Government.

Tramways.

Tramways.—The obvious advantages, quite independent of steam power, offered by placing longitudinal rails on the ground for the traction of vehicles led to the introduction, in recent years, of a modified form of railway, known as tramroads. In reality, tramroads are the oldest railways. Wooden rails existed in the mining and quarrying districts of England as early as the commencement of the 18th century, and these being liable to rapid destruction by wear and tear, it occurred to the manager of the far-famed Colebrookdale works before referred to that iron would be an excellent substitute for wood. Accordingly, in 1767, the whole of the wooden rails used on the extensive grounds over which the factories extended were taken up, and replaced by iron rails. Early as thus was the establishment of iron tramroads, over which vehicles were drawn by horses, into England, they were forgotten over steam-worked railways, and nearly a century elapsed before they were introduced again. The first tramway was laid down at Birkenhead, in 1860, after American models; but a subsequent attempt to lay down a line in London, from the Marble Arch to Bayswater, and another from Westminster Bridge southwards, proved a failure. Fresh attempts, made in 1868, were more successful; and in 1870 an Act was passed by the legislature—33 and 34 Vict. c. 78—to facilitate the construction of tramways throughout the country. This led to the laying down of "street railways" in nearly all the large towns. According to a return laid before the House of Commons in the session of 1878, the total length of tramways authorized by parliament up to the 30th of June, 1877, was 363 miles, and the total length opened for traffic 213 miles, comprising 125 miles of double lines, and 88 miles of single lines. The total authorized capital of all the tramway companies on the 30th June, 1877, was £5,528,989, while the paid-up capital amounted to £3,269,744, and the capital actually expended to £3,343,265. A parliamentary commission on tramways, which made its report in the session of 1877, recommended the introduction of steam as a motive power, and the probable adoption of this improvement can scarcely fail to bring "street railways," in course of time, to be a useful appendage of the ordinary railway system.

Canals.

Canals.—Roads and canals, too, the oldest aids to intercommunication, are tending more and more, as far as lengthened distances are concerned, to be simple auxiliaries of railways. The total length of the canals traversing England extends over 2360 miles, and it is estimated that more than half of this length already either belongs to railway companies or is under their control, while the remainder must follow the same tendency of absorption, as the traffic on them, even for the heavy goods, is unable to withstand the competition of railways. Various attempts to introduce steam on the canals have not met with success, being opposed by the size and construction of most of them, and the hindrance of numerous locks, dividing unequal levels.

Turnpike roads.

Roads.—Railways have rather aided than prevented the extension and improvement of the old highways of England, the turnpike roads, which are now acknowledged to be among the best in the world. But the "turnpikes" themselves have almost become things of the past. The system of road-building by private enterprise, the undertakers being rewarded by tolls levied from vehicles, persons, or animals using the roads, was established in England in 1663, an Act of Charles II., 15, c. 1, authorizing the taking of such tolls at "turnpikes" in Herts and Cambridgeshire. A century after, in 1767, the authorization was extended over the whole kingdom, by Act 7 George III. c. 40. In its fulness, the system lasted just sixty years, for the first breach in it was made by an Act 7 and 8 George IV. c. 24, passed in 1827, by which the chief turnpikes in the metropolis were abolished. Further Acts in the same direction followed, leading to the gradual extinction, by due compensation of the persons interested, of the old system, the maintenance of the roads being vested in "turnpike trusts and highway boards," empowered to levy local rates. The revenue of these boards, outside the metropolis, amounted to £2,302,869 in 1870, and had risen to over three millions sterling in 1876.

VIII. *Post and Telegraphs.*

The post-office as a Government department.

It is one of the main arguments of the advocates of the purchase of all the railways by the state, that vast undertakings, in which the whole nation is deeply interested, ought not to be left to private enterprise, aiming at gain chiefly; and that such concerns not only can be, but mostly are, better managed by the Government. The argument rests on the post-office. On all sides it is admitted that the creation and maintenance of the post-office as it now exists, burdened with an immense amount of work besides the mere carrying of correspondence, is a striking instance of the successful interference of Government in commercial affairs; while it is difficult to imagine how the same result could have been achieved by private persons. So general is this belief that all the states not only of Europe, but of the civilized world, have made the English post-office their model, closely imitating its whole organization.

Origin of the post-office.

In its present form, the post-office is an entirely modern creation, though the first regular arrangements for despatching letters to all parts of the kingdom date back to the year 1635, when the "letter office for England and Scotland" was established. But the system thus inaugurated, also based upon a Government monopoly, existing as such to the present time, remained long practically a private enterprise, the right of conveying letters and packets being let by contract to privileged individuals, whose sole aim was to make the greatest profit out of the undertaking. The first radical reform of the system, which laid the foundation of the present organization, was made by the Act 1 Vict. c. 32, confirmed July 12, 1837, which repealed all the old enactments relating to the post-office in favor of an entirely new legislation. This important Act was followed by another, 2 and 3 Vict. c. 52, confirmed August 17, 1839, which established a uniform rate of postage of one penny on inland letters, repealing at the same time the old and much-abused system of "franking" letters, exercised by members of parliament and others since 1660. The Act came into operation on the 10th of January, 1840.

Increase of correspondence from 1839 to 1876.

The vast increase in correspondence following upon the new organization is shown in the subjoined table, which gives the estimated number of letters in 1839 and 1840, and the ascertained number in quinquennial periods from 1841 to 1870, and for each of the six years from 1871 to 1876 in England and in the United Kingdom, together with the average number of the letters to each person, according to the returns of the postmaster-general:—

Years and Periods.	Total in England and Wales.	Average Number to each Person.	Total in United Kingdom.	Average Number to each Person.
Estimated No. of letters, 1839	60,000,000	4	76,000,000	3
" " franks, 1839	5,172,000		6,563,000	
" " letters. 1840	132,000,000	8	169,000,000	7
Average of 5 years, 1841–45...	179,000,000	11	227,000,000	8
" " 1846–50...	259,000,000	15	327,000,000	12
' " 1851–55...	330,000,000	18	410,000,000	15
" " 1856–60...	427,000,000	22	523,000,000	18
" " 1861–65...	534,000,000	29	648,000,000	22
" " 1866–70...	664,000,000	31	800,000,000	26
Year 1871..............................	721,000,000	32	867,000,000	27
" 1872..............................	737,000,000	32	885,000,000	28
" 1873..............................	756,000,000	32	907,000,000	29
" 1874..............................	804,053,100	33	967,503,300	30
" 1875..............................	846,852,400	35	1,008,392,100	31
" 1876..............................	856,042,400	35	1,018,955,200	31

Letters, post-cards, and newspapers.

The following table gives the number of letters, the number of post-cards, and the number of book-packets and newspapers, distributed by the post-office in each of the three divisions of the United Kingdom in the year 1876:—

Divisions.	Number of Letters.	Number of Post-Cards.	Number of Book Packets and Newspapers.
England and Wales	856,042,400	78,412,100	241,866,100
Ireland	71,792,100	4,883,500	24,146,600
Scotland	91,120,700	9,640,100	32,778,100
United Kingdom	1,018,955,200	92,935,700	298,790,800

Letters and population.

The average number of letters for each individual of the population in the year 1876 was 35 in England and Wales, 26 in Scotland, and 13 in Ireland.

The estimated number of newspapers delivered in 1876 was 125,065,800. Halfpenny postal cards came into use from the 1st of October, 1870, and foreign post-cards were first issued in 1875, under the International Postal Treaty of Bern, to which the adhesion of the British Government was given on the 30th September, 1874.

Money-orders from 1871 to 1876–77.

Money-Orders.—With the increase of the work of the post-office, and the success with which it was performed, more and more duties were laid upon it by the Government. The first of these was the money-order system, under which persons were enabled to hand the money in at one post-office for payment at another office. After the system had been tried from the year 1839 in the United Kingdom, it was extended to the colonies in 1856, and to foreign countries in 1869. The following table gives the total number and amount of money-orders, inland, colonial, and foreign, issued by the post-office in each of the years, ending December 31, from 1871 to 1875, and in the financial year ended March 31, 1877:—

Years.	Total of Inland, Colonial, and Foreign Orders.		Increase per cent. in Number.	Increase per cent. in Amount.
	Number.	Amount.		
		£		
1871	12,253,528	22,573,547	...	...
1872	14,242,612	25,019,683	16	11
1873	15,432,245	26,802,264	8	7
1874	16,221,503	27,507,672	5	$2\frac{1}{2}$
1875	16,819,874	27,688,255	$3\frac{7}{10}$	$\frac{7}{10}$
Year ended 31st March, 1877	18,179,922	28,702,375	$8\frac{1}{10}$	$3\frac{7}{10}$

Money-orders and population.

The enormous increase in the money-order business of the post-office since its establishment in 1839 is shown in the subjoined table, which gives the amount of money-orders issued in England and in the United Kingdom, and the number issued to each 100 of the population:—

Years and Periods.	England and Wales.		United Kingdom.	
	Amount.	Number of Money-Orders issued to each 100 of population.	Amount.	Number of Money-Orders issued to each 100 of population.
	£		£	
1839	240,063	0·9	313,124	0·7
1840	802,827	3·1	960,975	2·2
Average of 5 years 1841–45	4,211,885	12·3	4,937,255	8·9
" 1846–50	6,668,684	19·4	7,954,533	14·7
" 1851–55	8,488,175	23·9	9,941,316	18·9
" 1856–60	10,898,412	29·2	12,737,504	23·6
" 1861–65	14,021,757	32·9	16,398,361	27·1
" 1866–70	16,484,950	37·2	19,319,707	31·2
1871	18,566,317	45·1	21,799,583	38·2
1872	20,375,179	51·6	24,013,747	43·9
1873	21,629,750	55·0	25,600,069	47·1
1874	22,246,625	57·3	26,296,441	49·0
1875	22,397,716	58·6	26,497,918	50·3
Year ended Mar. 31, 1877	23,166,935	62·7	27,516,698	53·9

Foreign and colonial money-orders.

The money-order business transacted with the British colonies and with foreign countries is about equal in importance, but the latter showed a far greater expansion in the years 1870 to 1876. The total number of colonial orders in 1870 was 143,211, transmitting £600,981; and in 1876 the number had risen to 145,838, but the amount fell to £572,752. On the other hand, the total number of foreign money-orders rose from 47,431, transmitting £172,983, in 1870 to 211,163, transmitting £612,925, in 1876. In the case of both colonial and foreign money-orders, the number and amount arriving from abroad are far greater than those sent away.

Post-office savings banks.

Savings Banks.—The post-office, besides issuing and paying money-orders, fulfils the duties of a national savings bank, and also of an insurance institution, granting life insurance policies and annuities. The post-office savings banks, established by Act of Parliament in 1861, held a total amount of £26,996,550, standing in the names of 1,702,374 depositors, at the end of 1876. The proportion of depositors to population at that date was one to 15 in England and Wales, one to 71 in Scotland, and one to 87 in Ireland. In the whole of the United Kingdom it was one to 19. The average daily number of deposits in the year 1876 was 10,347, and the average amount standing to the credit of depositors, £15 17s. 1d. It is a notable fact that, although the majority of depositors undoubtedly belong to the laboring classes, including servants, the transactions of the post-office savings bank are much larger in winter than in summer. The greatest number of deposits in the year 1876 occurred on the 31st January, when it reached 25,063, considerably more than double the average daily number. There were 5448 post-offices open as savings banks at the end of 1876. (See page 232 below.)

Post-office life insurance and annuities.

Life Assurance.—While the post-office savings banks proved a great success, ever growing, and evidently much appreciated by the public, the same cannot be said about the life insurance and annuity department. It showed some vitality in the first few years after its establishment, from 1865 to 1872, but after this date both the insurance and annuity contracts greatly declined. In 1872 the number of life policies granted was 757, insuring £55,982; while in 1876 the number had fallen to 270, insuring £22,875. During the same period the number of annuity contracts fell from 1057 in 1872 to 758 in 1876, the total receipts in the latter year, both for immediate and deferred annuities, not amounting to more than £111,775. The almost insignificant amount of the transactions seems to show that this department of the post-office has no vitality, the field being already fully occupied by private enterprise.

Postal telegraph system.

Telegraphs.—Subsequent to the establishment of the money-order, the savings banks, and the insurance departments, a business of immense importance was added to the functions of the post-office in the control and management of all the telegraphs of the kingdom. It was not without much doubt and misgiving that parliament consented to add to the Government monopoly of conveying letters that of sending messages by electric wires; but after long discussions in 1866 and 1867, the system was approved of by the legislature the year after. An Act, 31 and 32 Vict. c. 110, authorizing the purchase of all the telegraphs by the Government, for the purpose of being added to the machinery of the post-office, was passed in the session of 1868, receiving the royal assent on the 31st of July. It was followed by another statute, 32 and 33 Vict. c. 73, establishing the monopoly. The chief reasons for passing the Act of 1868 were given in the preamble, which declared that "it would be attended with great advantage to the state, as well as to merchants and traders, and to the public generally, if a cheaper, more widely extended, and more expeditious system of telegraphy were established, and to that end [it is recommended that] the postmaster-general be empowered to work telegraphs in connection with the administration of the post-office." It was stated in parliament during the debates on the Act that, under the then existing system of private telegraph companies, severely competing with each other for the most remunerative business, there were 700 towns in the kingdom having a surplus service, each being attended to by two, three, or more companies, with offices close together, in the central parts; while, on the other hand, there existed 486 towns with no telegraphic facilities, except, perhaps, that offered by the nearest railway station. It was this fact which weighed, more than any other, in giving the future control of the telegraphs to the post-office, to be worked as a state monopoly.

Transfer of all private telegraphs to the post-office.

There were, when the Act of 1868 was passed, 13 telegraph companies in existence within the United Kingdom, including several which owned submarine cables for international service. There were, besides, 83 railway companies possessing electric telegraphs, for the use of the public as well as their own service. Altogether, these 83 railway companies had constructed for themselves 5157 miles of lines, comprising 16,191 miles of wire, with 1226 stations for public use; while the 13 telegraph companies possessed 16,879 miles of land lines, made up of 79,646 miles of wire, besides 4688 miles of submarine cable, containing 8122 miles of wire imbedded, with 2155 stations. Under the Act of Parliament, only 3 telegraph companies, the Electric, the British and Irish Magnetic, and the United Kingdom Telegraphic, had specified sums allowed to them for their property, and with all the rest the purchase-money had to be settled by agreement, if requisite through an arbitrator appointed by the Board of Trade. It necessarily took some time to settle these matters, which involved payment of over six millions sterling; but the task was accomplished, on the whole, with remarkable rapidity; and on the 5th of February, 1870, the post-office commenced the working of all the telegraph lines of the United Kingdom.

Postal telegraphs from 1870 to 1876–77.

The vast increase of telegraphic communication immediately after the new state organization, and its subsequent progress, is shown in the subjoined table, which gives the total number of messages forwarded from the year 1870—commencing February 5—to the 31st of March, 1877, the last period comprising fifteen months, to bring, as previously explained, the postal accounts into uniformity with the general financial accounts of the kingdom:—

Year ended	Number of Messages.		
	England and Wales.	Scotland.	Ireland.
31st December, 1870	4,655,627	955,116	533,950
30th December, 1871	6,300,867	1,305,596	800,328
28th December, 1872	7,664,463	1,677,203	1,118,092
27th December, 1873	8,963,818	1,942,610	1,280,731
26th December, 1874	10,034,685	2,141,030	1,363,195
25th December, 1875	10,775,279	2,272,465	1,434,996
15 months ended 31st March, 1877	13,485,279	2,905,242	1,861,811

Postal telegraph offices.

More than one-half of the whole number of messages of England and Wales forwarded by post-office telegraphs are metropolitan. The number of London messages was 2,462,039 in 1870, and rose to 4,398,262 in 1872, to 5,577,724 in 1874, and to 8,188,107 in the 15 months ended the 31st March, 1877. The number of post-offices open for the transaction of telegraph business in the United Kingdom on the 31st of March, 1877, was 3734, in addition to which messages were received at and delivered from 1636 railway stations. The staff exclusively engaged on telegraph duties numbered 11,654, comprising 21 superior officers, 6656 clerks, and 4977 messengers.

Working of postal telegraphs.

By the terms of the Act of 1868, establishing the system of postal telegraphs, all the railway companies retain the privilege of transmitting messages relating to their own service free of charge, on the wires running along their lines. To the public a uniform rate of transmission is charged, irrespective of distance. The charge was fixed, provisionally, at one shilling for every twenty words, and three pence for every additional word, the names and addresses of senders and receivers not being included in the number. The payments were originally made in postage stamps; but on the 1st of April, 1876, distinctive telegraph stamps for the prepayment of messages were introduced. Forms of receipts for messages were brought into use on the 1st of February of the same year, but it was stated in the twenty-third report of the postmaster-general, dated August 4, 1877, that up to that time "very little use had been made" of this innovation by the public.

The subjoined table gives the total receipts and the net revenue of the postal telegraphs, from their establishment, on the 5th of February, 1870, to the end of the financial year 1876–77:—

Receipts and Expenditures of Telegraph Department.

Years ended 31st March.	Total Telegraph Revenue.	Telegraph Working Expenses.	Net Revenue.
	£	£	£
1870 (2 months)	100,760	62,273	38,487
1871	696,934	394,477	303,457
1872	751,611	591,776	159,835
1873	989,921	874,946	114,975
1874	1,083,466	967,790	115,676
1875	1,137,079	1,077,347	59,732
1876	1,276,662	1,031,524	245,116
1877	1,313,107	1,123,257	189,850

Revenue and expenditure of the post-office, exclusive of telegraphs.

The total gross receipts of the post-office, from postage, money-orders, and other sources, exclusive of telegraphs, in the financial year ending March 31, 1877, amounted to £6,017,072, and the total expenditure to £4,070,006, leaving a net revenue of £1,947,066. In the year 1840, the date of the introduction of the "penny post" and the establishment of the post-office on its present organization, the total gross receipts were £1,359,466, while the net revenue was £500,789. The gross receipts increased at a much larger rate within the period from 1840 to 1877 than the net receipts, which latter fell for some years, notably from 1867 to 1871, through great and costly improvements being made in the service. The chief branches of expenditure in the year ended March 31, 1877, were £2,046,065 for salaries, wages, and pensions; £779,632 for conveyance of letters and packets by mail boats and private ships; £684,465 for conveyance of letters by railways; and £171,370 for the same service done by coaches, carts, and other vehicles. The total expenditure of the money-order department in the year ended March 31, 1877, resulted, according to the report of the postmaster-general before cited, in a loss of £10,000, which deficit was expected to be greater in future years, owing to "the large increase in the number of inland money-orders for small amounts, on which the commission is insufficient to cover the cost of the service."

Staff of the post-office.

Staff.—The total staff of officers and servants employed by the post-office at the end of 1876 was 45,024, inclusive of 11,654 persons attending solely to telegraph duties. Of post-office clerks there were at the date 3380; of postmasters, 13,447; and of letter carriers, sorters, and post-office messengers, 16,327. In London alone, the staff of the post-office comprised 10,380 persons, of which number 5500 were attached to the chief offices in St. Martin's-le-Grand. In 1840 the total number of post-offices in the United Kingdom was 4500; and at the end of 1876 they had increased to 13,447, besides which there were 10,724 road letter-boxes. It is now an established fact that not any other Government department of modern times has succeeded like the post-office in the double task of augmenting the welfare of the nation and at the same time increasing the public revenue.

IX.—*National Revenue and Expenditure.—Taxation.*

Financial periods from 1827 to 1871.

The finances of no European state are in a more admirable condition than those of the United Kingdom. Not only is the national revenue, requisite to meet the expenditure, raised with the utmost facility, but for many years the balance of them has been complete, an annual surplus being the rule, and a deficit the exception, in most financial periods. In the half century intervening between the years 1827–28 and 1876–77, both the expenditure and revenue rose to but a comparatively small degree, far below all proportion with the vastly increased wealth of the nation during the same period. In the financial year 1827–28 the total public revenue amounted to £54,932,518, and the expenditure to £53,800,291; while in the financial year 1840–41 the total revenue was £47,433,399, and the total expenditure £49,285,396. Thus, in the course of thirteen years, the fiscal burdens laid upon the population, augmented by nearly two millions in the mean time, instead of being increased, had been greatly lessened. Subsequently, from 1841 to 1877, a gradually increasing expenditure took place, together with a rising public revenue; but the upward movement was slight, and much below the growth of the population in its numbers, and, still more, in wealth.

At the end of the next decennial period, in the financial year 1850–51, the total revenue had risen to £53,057,053, and the expenditure to £49,882,322; and at the end of another decennial period, in the financial year 1860–61, the revenue stood at £70,283,674, and the expenditure at £72,792,059. At the end of the next decennial period, in the financial year 1870–71, the total revenue had fallen to £69,945,220, and the expenditure to £69,548,539. During the whole of the thirty years from 1840–41 to 1870–71, there were but few annual periods without a surplus of revenue over expenditure.

Annual revenue and expenditure from 1841 to 1876.

The subjoined table shows the total revenue and the total expenditure of the government, together with the proportion of receipts per head of population of the United Kingdom, in every fifth financial year from 1841 to 1871, and each year thereafter to 1877. Up to 1854, the financial years ended April 5; but, commencing from 1855, the financial years ended March 31. Till the year ending March 31, 1856, the *net* revenue and expenditure were always given in the official returns; but, commencing with the year ending March 31, 1871, the accounts furnished, more correctly, the *gross* expenditure and revenue, the latter including charges for its collection:—

Years ended April 5th and March 31st.	Total Revenue.	Total Expenditure.	Proportion of Revenue per Head of Population of United Kingdom.		
	£	£	£	s.	d.
1841	47,433,399	49,285,396	1	15	9
1846	52,009,324	49,628,724	1	17	5
1851	53,057,053	49,882,322	1	18	6
1856	65,704,491	88,428,345	2	10	7
1861	70,283,674	72,792,059	2	8	10
1866	67,812,292	65,914,357	2	5	1
1871	69,945,220	69,548,539	2	4	5
1872	74,708,314	71,490,020	2	7	3
1873	76,608,770	70,714,448	2	8	2
1874	77,335,657	76,466,510	2	8	2
1875	74,921,873	74,328,040	2	6	3
1876	77,131,693	76,621,773	2	7	1
1877	78,565,036	78,125,227	2	7	6

Surplus and deficit periods.

The largest surplus in the course of the thirty-six years from 1840–41 to 1876–77 occurred in the financial year 1869–70, when the excess of revenue over expenditure amounted to £6,569,500, and the next largest in the financial year 1844–45, when the excess of income over expenditure was £6,342,436. On the other hand, the greatest deficit showed itself in the financial year 1855–56 when unforeseen war expenses brought the revenue below the expenditure to the extent of £22,723,854. The fifteen years from 1863 to 1877 showed all, with the exception of two, 1868 and 1869, a surplus of revenue over expenditure.

Sources of revenue in 1876–77.

The following table gives the official account of the gross sources of revenue of the United Kingdom for the financial year ended March 31, 1877:—

		£
Customs		19,922,000
Excise		27,736,000
Stamps		10,890,000
Land Tax and House Duty		2,532,000
Property and Income Tax		5,280,000
Post Office		6,000,000
Telegraph Service		1,305,000
Crown Lands (Net)		410,000
Miscellaneous:—	£	
Military and Naval extra Receipts and Proceeds of Old Stores sold	906,769	
Amount received from the Revenues of India on account of Charges for British Troops	868,330	
Interest on Public Loans	654,572	
Interest on the Purchase Money of the Suez Canal Shares	139,110	
Allowance out of Profits of Issue received from Bank of England	138,578	
Saving on vote of credit for Ashantee war	12,197	
Other Miscellaneous Receipts	1,770,480	
		4,490,034
Total Revenue		78,565,036

Branches of expenditure in 1876–77.

The following table gives the official account of the gross expenditure of the United Kingdom for the financial year ended March 31, 1877:—

Debt.	£	£
Interest and Management of the Permanent Debt	21,588,982	
Terminable Annuities	5,374,198	
Interest of Exchequer Bills	103,912	
Interest of Bank Advances for Deficiency	8,127	
New Sinking Fund	624,781	
		27,700,000
Interest on Local Loans		142,921
Interest, etc., on Exchequer Bonds (Suez)		149,912
Charges on Consolidated Fund.		
Civil List	406,710	
Annuities and Pensions	316,669	
Salaries and Allowances	96,850	
Courts of Justice	631,791	
Miscellaneous Charges	143,018	
		1,595,039
Supply Services.		
Army	15,251,355	
Charges for troops in India	170,000	
Army Purchase Commission	498,362	
Navy	11,364,383	
Ashantee Expedition	2,017	
Miscellaneous Civil Services	13,333,851	
Customs and Inland Revenue	2,766,279	
Post-Office	3,159,218	
Telegraph Service	1,141,000	
Packet Service	850,890	
		48,537,355
Total Expenditure		78,125,227

The surplus for the financial year 1876–77 amounted to £439,809, being less than in any of the preceding five years. In the budget estimates for 1877–78 the total revenue was calculated at £79,020,000, and the total expenditure at £78,794,044, leaving a surplus of £225,956.

Principal sources of revenue.

About three-fourths of the total revenue of the United Kingdom are derived from three sources of income—excise, customs duties, and stamps. In the sixteen financial years from 1861–62 the revenue from the excise increased greatly, and that from customs declined, while that from stamps increased moderately. The following table shows the receipts from these main sources of revenue for every third year from 1861–62 to 1876–77:—

Years ended 31st March.	Excise.	Customs.	Stamps.
	£	£	£
1862	18,332,000	23,674,000	8,590,945
1865	19,558,000	22,572,000	9,530,000
1868	20,162,000	22,650,000	9,541,000
1871	22,788,000	20,191,000	9,007,000
1874	27,172,000	20,339,000	10,550,000
1877	27,736,000	19,922,000	10,890,000

The excise as source of revenue.

Excise.—The vast increase in the receipts from the excise during the sixteen years from 1862 to 1877 was due solely to the corresponding increase in the consumption of spirituous liquors. The increase was greatest in the receipts from spirits, which rose from £9,618,291 in 1861–62 to £14,873,165 in 1876–77. The excise receipts from malt grew from £5,866,302 in 1861–62 to £8,040,378; and those from licenses to make and sell spirits and malt liquors from £1,500,613 in 1861–62 to £3,548,557 in 1876–77. In the latter financial year the receipts from the excise had come to represent already considerably more than one-third of the total revenue, and should the growth, very steady and regular from year to year, continue at the rate shown in the preceding table, it will not be long before one-half of the national income will be raised by the voluntary taxation of the consumers of alcoholic liquors.

Receipts from customs.

Customs.—The decline in the receipts from customs during the period 1862 to 1877 was due entirely to a constant reduction of duties. Those on tea were reduced in 1862, causing a loss to the revenue of £1,641,541; and again in 1864, when the loss was £2,214,981. The duties on sugar were also greatly reduced in 1863, the loss to the customs being £1,741,272;

and again in 1872, with a loss of £1,612,882; while the small remnant of the old duties on corn was repealed in 1868, at a loss of £855,581; and the example was followed in the case of the sugar duties, the last of which was abolished in 1875. Thus the sugar duties, producing £6,383,289 in 1861–62, brought nothing in 1876–77, while the tea duties fell from £5,516,584 to £3,723,147. Alone of all the customs duties, those on foreign spirits and wine increased during the period, notwithstanding the latter article also underwent a reduction of duties. Together, the foreign wine and spirits duties produced £3,753,785 in the financial year 1840–41, and £7,507,807 in 1876–77. Adding this sum to the excise receipts, the total revenue derived from spirituous liquors in the financial year 1876–77 was no less than £35,243,807, or nearly three-sevenths of the national revenue.

Changes in taxation.

The subjoined table exhibits the changes effected in the national revenue by either the repeal or reduction of taxes, and the imposition or re-imposition of old and new ones, during the period from 1861–62 to 1876–77:—

	Repealed or Reduced.	Imposed.	Actual Diminution (—) or addition (+)
	£	£	£
Customs	14,263,282	11,034	— 14,252,248
Excise	1,381,000	1,870,000	+ 489,000
Property and Income Tax	17,158,000	7,916,000	— 9,242,000
Other Taxes	1,272,933	...	— 1,272,933
Stamps (including Succession Duty)	2,427,400	20,500	— 2,406,900
Total	36,502,615	9,817,534	— 26,685,081

The income tax.

Income Tax.—The basis and principle of the system of levying the national revenue is indirect taxation, or, as it may very properly be called, voluntary taxation, since at present no impost lies upon any article of prime necessity. To this system the only exception is the income tax, which, however, has many opponents, and is barely considered by the legislature a permanent tax, as it has to undergo constant changes, all tending to its repeal at a favorable opportunity. Originally granted by parliament, against great opposition, in 1798, as "an aid for the prosecution of the war" against France, the old income tax was repealed in 1816. But it was reimposed, under modified forms, in 1842, nominally for only three years, the amount being fixed at 7d. in the pound. Subsequently parliament consented to new prolongations, alternately of three years, of one year, and of seven years; and in the course of the Crimean war, the impost was raised, first to 14d., and then to 16d., in the pound. In 1857 the income tax was again reduced to 7d., and in 1858 to 8d., in the pound. In the following year it was once more raised to 9d., and to 10d. in 1860; but was again reduced to 9d. in the pound in 1861, to 7d. in 1863, to 6d. in 1864, and to 4d. in 1865. In 1867 the tax was again raised to 5d., and in 1868 to 6d., but in the following year once more lowered to 5d., and in 1870 to 4d., in the pound. The tax was again brought up to 6d. in 1871, but lowered to 4d. in 1872, to 3d. in 1873, and to 2d. in 1874. Finally, in 1876 it was once more raised to 3d. in the pound, but at the same time restricted to incomes of over £150 per annum, with a deduction of £120 for all incomes between £150 and £400, thus affecting mainly the so-called "upper" and "upper middle" classes of the population. The total receipts of the income tax amounted to £10,365,000 in the financial year 1861–62, and had sunk to £5,280,000, or little more than one-half, in the year 1876–77.

Revenue, 1876–77.	England.	Scotland.	Ireland.
	£	£	£
Spirits	13,078,101	4,056,331	3,507,985
Malt	7,220,089	368,343	451,950
Wine and beer (customs)	1,894,856	124,309	211,078
Excise Licenses	3,034,395	308,599	205,563
Tobacco	6,014,114	737,227	1,024,231
Tea and Coffee	3,206.765	322,156	394,644
Land and house duty	2,404,792	133,382	....
Income tax	4,342,410	518,149	269,889
Stamps	8,581,581	1,110,807	589,173
Miscellaneous items	1,324,787	77,910	10,208
Total	51,101,890	7,757,213	6,664,724
Per head of population	£2 1 8½	£2 3 6¾	£1 4 11¾

An indication of the proportions of the revenue derived from taxation in England, Scotland, and Ireland respectively is given in the preceding table. The figures, which are for the year ending March 31, 1877, do not include the post-office returns, and in the case of the income tax are exclusive of the returns from the incomes of Government officials.

Principal branches of expenditure.

Expenditure.—As the main sources of national revenue are but few, so are the principal branches of expenditure. They may be reduced to three, nemely,—first, the interest and management of the national debt; secondly, the charges for the army and the navy; and thirdly, the cost of the general government, entered in the financial accounts under the headings of "Civil List," "Miscellaneous Civil Services," and other charges placed to the Consolidated Fund. The following table exhibits the annual disbursement under each of these three principal branches of national expenditure, during every third financial year from 1861–62 to 1876–77:—

Financial Years ended 31st March.	Interest and Management of Debt.	Army and Navy.	Civil List and Civil Charges of all kinds.
	£	£	£
1862	26,330,684	29,452,342	10,821,956
1865	26,369,398	25,280,925	10,205,412
1868	26,571,750	28,587,531	11,193,758
1871	26,826,437	24,237,041	13,176,659
1874	26,706,726	26,220,864	17,067,609
1877	27,992,834	27,286,117	15,779,779

Growth of the national debt.

National Debt.—It will be seen that, leaving alone the cost of the army and navy—of which more in the next chapter—the charges for the interest and management of the debt form by far the most important branch of national expenditure. The foundation of this debt, larger than that of any other country in the world, and the burden of which could be safely borne only by the wealthiest of nations, was laid at the time of the Revolution, in 1689, and its growth since that time, both as regards capital and interest, is shown in the following table:—

Historical Periods.	Capital of Debt.	Interest and Management.
	£	£
Debt at the Revolution, in 1689	664,263	39,855
Excess of debt contracted during the reign of William III. above debt paid off	15,730,439	1,271,087
Debt at the accession of Queen Anne, in 1702	16,394,702	1,310,942
Debt contracted during Queen Anne's reign	37,750,661	2,040,416
Debt at the accession of George I., in 1714.	54,145,363	3,351,358
Debt paid off during the reign of George I., above debt contracted	2,053,125	1,133,807
Debt at the accession of George II., in 1727.	52,092,238	2,217,551
Debt contracted from the accession of George II. till the peace of Paris in 1763, three years after the accession of George III	86,773,192	2,634,500
Debt in 1763	138,865,430	4,852,051
Paid during peace, from 1763 to 1775	10,281,795	380,480
Debt at the commencement of the American war, in 1775	128,583,635	4,471,571
Debt contracted during the American war.	121,267,993	4,980,201
Debt at the conclusion of the American war, in 1784	249,851,628	9,451,772
Paid during peace from 1784 to 1793	10,501,380	243,277
Debt at the commencement of the French war, in 1793	239,350,148	9,208,495
Debt contracted during the French war	601,500,343	22,829,696
Total funded and unfunded debt on the 1st of February, 1817, when the English and Irish Exchequers were consolidated	840,850,491	32,038,191
Debt cancelled from the 1st of February, 1817, to 5th of January, 1836	53,211,675	2,894,674
Debt and charge thereon on 5th of January, 1836	787,638,816	29,143,517
Debt and charge thereon on 31st of March, 1861	824,607,459	26,335,114

The following table exhibits the amounts of capital of the debt, distinguishing funded and unfunded, during each of the sixteen years from 1861–62 to 1876–77 :—

Capital of the National Debt from 1862 to 1877.

Financial Years ended 31st March.	Capital of Funded Debt.	Capital of Unfunded Debt.	Total Capital of National Debt, inclusive of Terminable Annuities.
	£	£	£
1862	788,229,618	16,517,900	824,136,394
1863	787,422,928	16,495,400	824,635,055
1864	781,712,401	13,136,000	821,290,829
1865	780,202,104	10,742,500	816,352,974
1866	773,941,190	8,187,700	807,563,924
1867	770,188,625	7,956,800	805,666,938
1868	741,844,981	7,911,100	806,572,884
1869	741,112,640	8,896,100	805,480,164
1870	741,514,681	6,761,500	801,406,561
1871	732,043,270	6,091,000	796,104,155
1872	731,756,962	5,155,100	792,661,132
1873	727,374,082	4,829,100	785,761,762
1874	723,514,005	4,479,600	779,283,245
1875	714,797,715	5,239,000	775,348,386
1876	713,657,517	11,401,800	776,970,544
1877	712,621,355	13,943,800	775,873,713

Terminable annuities and sinking fund.

The amount of terminable annuities, included in the total capital of the debt, by computation in 3 per cent. stock, varied considerably in different years, through additions being made to them, as in 1864, when £5,000,000 of the funded debt were converted into terminable annuities, and again in 1875, when £4,000,000 of Suez Canal bonds were added. The total computed capital of them amounted to £49,308,558 on the 31st of March, 1877. By the provisions of an Act of Parliament passed in the session of 1875, the national debt will be gradually reduced by the establishment of a new permanent sinking fund, maintained by annual grants. The grants, by the same Act, were fixed at £27,400,000 for the financial year, 1875–76, at £27,700,000 for the year 1876–77, and at £28,000,000 for every subsequent year after 1877.

Comparison of revenue and expenditure.

There is a somewhat remarkable harmony between the chief sources of revenue and the principal branches of expenditure. Thus in the financial year 1876–77 the first source of revenue, excise, productive of £27,736,000, almost exactly covered the first branch of expenditure, interest and management of debt, amounting to £27,992,834. Again, in the same financial year, the receipts from customs and stamps paid, with a surplus left, for the cost of the army and navy; while the produce of the taxes, including income tax, together with the post-office, discharged the expenses of the general government.

Local taxation.

Local Taxation.—Besides the national or so-called imperial taxation, a sum considerably surpassing the total receipts from the excise is raised annually by local taxation. In the financial year ended March 31, 1874—the last for which returns were published at the end of 1877—the total amount raised by taxes, and from other sources of income, for the purposes of local government, in each of the three divisions of the United Kingdom, was as follows :—

Divisions.	Local Taxes.		
	Levied by Rates.	From Tolls, Dues, etc.	Total of Taxes.
	£	£	£
England and Wales	19,773,122	4,105,907	23,879,029
Scotland (partly estimated)	1,908,210	464,347	2,372,557
Ireland..........................	2,640,737	355,272	2,996,009
Total for United Kingdom	24,322,069	4,925,526	29,247,595

In addition to the sums here specified, the local authorities raised in the financial year 1873–74 the amount of £1,552,555 from sales and rents of property, £2,404,675 from Government contributions, £8,480,486 by loans, and £3,848,504 from miscellaneous sources. The total local receipts, including taxes, amounted in the year to £45,533,815,—of which £37,731,193 was contributed by England and Wales, £3,202,714 by Scotland, and £4,599,908 by Ireland.

Taxation per head of population.

From a parliamentary paper, comparing imperial and local taxation in the United Kingdom, issued in the session of 1876, it appears that the burden of local taxation is much higher in England and Wales than either in Scotland or in Ireland. If spread evenly over the three divisions of the United Kingdom, it amounted in 1873–74 to £2 18s. 11d. per head of the total population.

X. *Army and Navy.*

Cost of the army and navy.

About one-fifth of the entire national expenditure is for the maintenance of the army, and an additional one-seventh for that of the navy. In the army estimates for the financial year ending the 31st March, 1878, sanctioned by parliament, the total amount to be expended on account of the army was fixed at £14,583,700, of which £12,643,900 was for "effective services," that is, the actual maintainance of the regular army, as well as auxiliary and reserve forces, and £1,894,800 for "auxiliary services," comprising rewards, pensions, and superannuation allowances.

Army estimates for 1877–78.

The regular army was composed, according to the army estimates of 1877–78, of 7153 commissioned officers, 16,968 non-commissioned officers, and 109,599 rank and file, being a total of 133,720 men of all ranks, as follows :—

Branches of the Military Service.	Officers.	Non-commissioned officers, trumpeters, and drummers.	Rank and file.
Officers on the General and Departmental Staff:—			
General staff........................	91	90	....

Total force, officers and men, the cost of which is defrayed from Army Grants.	7,153	16,968	109,599

Numbers of the army at home from 1800 to 1876.

The numbers of the regular army, maintained for service in the United Kingdom, have varied much in the course of the present century. In the year 1800 the total was 70,745 ; and it rose to 106,331 in 1805, and to 112,518 in 1810. Within the next three quinquennial periods, the number decreased, that is, to 80,731 in 1815, to 61,116 in 1820, and to 46,264 in 1825. In 1830 the number rose again to 48,094, but fell to 47,214 in 1835. There was another rise to 50,476 in 1840, to 59,870 in 1845, and to 67,077 in 1850. In 1855 the number had fallen once more to 49,342, but this was the lowest point it reached. The strength of the army rose again to 89,507 in 1860; it stood at 78,410 in 1865, and at 84,361 in 1870. There were considerable fluctuations in the number of men maintained for home service in each of the years from 1871 to 1876. The number was 82,472 at the end of 1871, 94,402 in 1872, 101,145 in 1873, 98,719 in 1874, 92,386 in 1875, and 96,275 in 1876. Of the total force in the United Kingdom in 1876, there were 68,253 men in England and Wales, 3895 in Scotland, 22,414 in Ireland, and 1713 in the Channel Islands.

Troops on colonial service.

The numbers of regular troops on colonial service were gradually diminished in recent years. They were entirely withdrawn from Australia and New Zealand, and partly from British North America, a small force only being left in Nova Scotia. The chief military stations left were Malta, Gibraltar, the Cape of Good Hope, Ceylon, Bermuda, and Hong Kong. The total number of the British forces in India was given at 62,652 men of all ranks in the army estimates of 1877–78.

Recruits.

The recruits for the regular army were raised as follows from each of the divisions of the United Kingdom in the years 1871 to 1873:—

Years.	England and Wales.	Scotland.	Ireland.	United Kingdom.
1871	18,015	1,547	2,365	21,927
1872	14,525	1,096	1,886	17,507
1873	13,431	1,057	2,114	16,602

Desertions.

Desertions from the army, mainly if not entirely by recruits, were formerly extremely numerous. But they tended to diminish in recent years, partly on account of improved organization, under which better treatment is secured to the rank and file of soldiers, and partly by the option given to recruits to enlist either for "long" service of twelve years, or for "short" service of six years. In the year 1862 there were 4624 recruits approved, and among them there were no fewer than 2895 desertions, being more than one-half of the total; but from among the 21,927 recruits of 1871 there were but 5861 desertions, while from 20,640 recruits enlisted in the year 1874 there were only 5572 desertions. Of the recruits of 1874, there enlisted 7784 on "long" service, and 12,856 on "short" service.

Militia, yeomanry, and volunteers.

The army estimates enumerate, as constituting the forces of the United Kingdom, besides the regular troops, four other bodies, classified as reserves, or auxiliary troops. These are—the militia, the yeomanry cavalry, the volunteer corps, and the enrolled pensioners and army reserve force. The total number of the militia in 1877–78 was returned at 139,331, comprising a permanent staff of 4831, and 134,500 men in training service. For the same period the total number of yeomanry cavalry was 14,830, there being a permanent staff of 282, and 14,548 yeomen. The total number of volunteers provided for in the army estimates of 1877–78 was 174,241, comprising 32,393 artillery volunteers, and 148,848 light horse, engineers, and rifle volunteers. Since its establishment, under a new organization, in the year 1859, down to the end of 1876, the total number of volunteers who joined and passed through the force was as follows, according to a report laid before parliament in the session of 1877:—

Volunteers.	Total Number from 1859 to 1876.
Light Horse	515
Artillery	124,897
Engineers	20,739
Mounted Rifles	262
Rifle Volunteers	486,498
Total	632,911

Enrolled pensioners.

The fourth and last branch of the reserves or auxiliary troops of the United Kingdom, the enrolled pensioners, were returned as numbering 36,000 in the army estimates of 1877–78. The enrolled pensioners are divided into two classes, 15,000 men forming the first, and 21,000 men the second division.

Army expenditure from 1840–41 to 1877–78.

Army Expenditure.—The expenditure for the army, after nearly doubling from 1840–41 to 1861–62, remained almost stationary in the sixteen financial years from 1861–62 to 1876–77. It amounted to £15,570,869 in 1861–62, and, gradually decreasing, fell to £13,804,450 in 1865–66, after which it rose again to £15,482,582. It sank once more to £13,430,400 in 1870–71, but rose in the financial year 1872–73 to £14,824,500; and changed little till the year 1876–77, when the disbursements for the army amounted to £15,749,717. The largest branch of expenditure is that for the general staff and regimental pay, for which £4,565,800 was set down in the army estimates of 1877–78; and the next largest branch for provisions, transport, and other services, fixed at £2,986,000 for the same year. The total cost of the auxiliary and reserve forces for the year 1877–78 was not more than £1,209,100, of which £534,000 was for the militia, £74,400 for the yeomanry cavalry, £468,700 for the volunteer corps, and £132,000 for the enrolled pensioners and army reserve force.

Naval expenditure from 1840 to 1877.

Naval Expenditure.—Although considered "the bulwark of the nation," and more important for the defence of the kingdom than its land forces, the navy is maintained at much less expense. However, the disbursements for the navy increased very largely since the year 1840, when the old wooden "three-deckers," formerly the pride of the seas, had to disappear, to give way, first to iron ships propelled by steam, and, not long after, to armor-clad men-of-war, gradually assuming the shape of floating fortresses. In the financial year 1840–41 the total expenditure on account of the navy, including transport service, was £5,597,511; and in the next year, 1841–42, the cost rose to £6,489,074. In 1845–46 the naval expenditure had risen to £6,809,872, in 1846–47 to £7,803,465, and in 1847–48 to £8,013,873. After 1848 the expenditure for the navy remained nearly stationary for six years, till 1854, when it suddenly rose, with the setting in of the era of armor-clad ships. In the financial year 1854–55 the naval expenditure went up, with a leap, to £14,490,105; and in the next year, 1855–56, it reached the large sum of £19,654,585, an amount unparalleled before or since. The next few years showed a great reduction in naval expenditure, which fell to £13,459,013 in 1856–57 to £10,590,000 in 1857–58, and to £9,215,487 in 1858–59. There was another rise to £11,823,859 in 1859–60, and to £13,331,668 in 1860–61; but this was followed by a decrease to £12,598,042 in 1861–62, and to £11,370,588 in 1862–63. At the latter amount the expenditure for the navy remained, with unimportant fluctuations, till 1877, never rising much above 12 millions, nor sinking much below 10 millions. The naval expenditure amounted to £11,364,383 in the financial year ended March 31, 1877.

Number of ships in commission.

Navy.—In the naval estimates for the financial year 1877–78, voted by parliament, the total expenditure was fixed at £10,979,829, and in them the strength of the navy of the United Kingdom, regarding ships in commission, was reported as follows for December 1, 1876.

Ships in Commission.

Sea-going steamers:—		
Iron-clad line-of-battle ships	4	
Iron-clad frigates and corvettes	13	
Other " " "	30	
Sloops and small vessels	65	
Total sea-going steamers		112
Reserve steamers and sailing vessels:—		
First reserve steamers	9	
Receiving and dépôt steamers	6	
" " " sailing vessels	13	
Surveying steamers	3	
Troop ships, steamers	5	
Store ships, steamers	3	
Tenders, steamers	38	
" sailing vessels	6	
Coast-guard cruisers, steamers	4	
" " sailing vessels	20	
Gunnery training vessels, and sloops, sailing	9	
Drill ships for the Naval Reserve	8	
Total reserve steamers and sailing vessels		136
Total navy		248

Armor-clad ships.

The number of ships in commission here given form but a small portion of the naval forces of the United Kingdom, especially of its by far most important division, the armor-clad fleet. Together with the navy estimates for the financial year 1877–78, there was issued a parliamentary return, issued from the Admiralty, dated April 5, 1877, containing a list "of all iron-clads, and date of their first completion for sea." The return gives the names of 48 armor-clad vessels, 31 of them classified as "broadside ships," one as a "ram," 14 as "turret ships," and 2 as "iron-clads building."

Increase of armor thickness in iron-clads.

The whole of the armor-clad ships of the broadside class completed previous to 1870 have no thicker armor than from 4½ to 5½ inches; while those completed from 1870 to 1873 received armor of from 6 to 8 inches thickness. This was increased in the broadside iron-clad of 1877, the "Alexandra," to from 8 to 12 inches thickness; and in three not quite completed, to armor of from 8 to 10 and 11 inches. In the turret ships a greater thickness of armor was resorted to at an earlier date. The "Glatton," completed in 1872, was the first ship to receive armor of from 12 to 14 inches in thickness, subsequently also given to the "Devastation" and the "Thunderer;" while the "Dreadnought" had 14 inches throughout. Surpassing all other ships in armor-thickness is the "Inflexible," under construction at the end of 1877, the central part of which has from 16 to 24 inches, protecting 4 guns of 81 ton weight, the heaviest ever made for the British navy, and exceeded only by a few made in England for two Italian men-of-war.

Unarmored ships.

The construction of unarmored ships, while not yet quite abandoned, is confined entirely to screw steamers, built of iron or steel, designed for great speed, and with very powerful engines. There were 9 ships of this class at the end of 1877, 3 of them frigates and six corvettes. The two largest frigates, the "Inconstant" and the "Shah," of 5700 tons, with engines of 7500 horse-power, were reported at the date to be the swiftest ships of the British navy.

Number of men and of officers in the naval service.

The number of men provided for the naval service of the kingdom was 54,400 in the navy estimates 1877–78. They were divided into 34,100 seamen and 6300 boys, 3000 of the latter being under training, giving a total of 40,400 directly classified as "sailors." Besides them, for the service of the fleet, were 14,000 marines—7000 afloat and 7000 on shore. Included in the number of 34,100 seamen of the fleet, provided for in the estimates of 1877–78, were 160 flag officers, 30 officers superintending dockyards and naval establishments, and 2889 other commissioned officers on active service, being a total of 3079 officers for the British navy.

XI. *Religion and Education.*

Want of religious statistics in England.

There is a singular want of authentic religious statistics in England. While in nearly all other European countries the number of the population adhering to various creeds is carefully ascertained at the periodical census-takings, or at other times, this has never been done in England, except in a cursory manner. At the census of March 31, 1851, an enumeration took place of the number of places of worship in England and Wales, and the attendance of persons therein on the preceding day, a Sunday; but the information thus obtained, though valuable in some respects, was not of the kind to allow accurate conclusions concerning the strength of the various religious bodies, it being well known that the attendance in churches and chapels comprises many persons outside the creed to which they adhere. The returns of the census of March, 1851, were as follows:—

Creeds.	Total Attendance. in Places of Worship.	Percentage of Attendance.
Church of England.........	2,971,258	47·4
Church of Rome.............	249,389	3·9
All other religious bodies.	3,135,575	48·7
Total	6,356,222	100·0

The total population of England and Wales at the census of March 31, 1851, was 17,927,609, so that the church attendance registered comprised little more than one-third of the population.

Marriages as a test of creed.

In the absence of other official reports, the best existing means of ascertaining the numbers of the various creeds are in the returns of the registrar-general of births, deaths, and marriages. Since the year 1836, when, during Lord Melbourne's administration, an Act was passed granting all dissenters from the state church the right to go through the ceremony of marriage in their own churches and chapels—a right of which they had been deprived from 1754, for a period of 82 years—strict accounts were kept of the creeds of all persons marrying, and from these tolerably accurate conclusions may be drawn regarding the respective numbers if not of all the sects and denominations, at least of the two great divisions of the population, churchmen and nonconformists. A careful analysis of the marriage returns for the forty years from 1837 to the end of 1876 makes it apparent that the number of nonconformists is steadily increasing, and that, although the great majority of the population still adhere to the Church of England, the probability seems that it will be otherwise in the course of one or two generations.

Dissenters from the Church of England.

Dissenters.—From an enumeration made in the year 1699, and believed to be quite trustworthy, it appears that at that time the total number of Protestant dissenters from the Church of England was not more than 214,000, being 4·18 per cent. of the population. There are no returns for about a century and a half after this date from which an estimate can be drawn respecting the number of dissenters, the first new basis for them not offering itself till the passing of the Marriage Act of 1836. In 1845, when the Act had been well carried out, the number of Protestant dissenters in England and Wales was calculated at 1,351,000, being 8·08 per cent. of the population. This was no great increase from 1699, when the percentage was 4·18, but the rise of dissent became more marked henceforth. In 1851 the number of Protestant dissenters was estimated at 1,958,000, or 10·89 per cent. of the population; and ten years after, in 1861, the total number was calculated to have increased to 3,090,000, being 15·36 per cent of the population. There was an estimated further increase to 3,686,000, or 17·38 per cent. of the population, in the number of dissenters at the end of 1866; while the last calculations, going down to the end of 1876, make it probable that at this date the number had risen to 4,500,000, being not far from 20 per cent. of the population. According to the most reliable estimates the dissenters did not constitute the majority of the population in the year 1876 in any part of England, but they possessed it in Wales. Next to Wales, the greatest number of dissenters were in Monmouthshire, Cumberland, Cornwall and Devon, Durham and Yorkshire, in all which counties they constituted more than a third of the population. On the other hand, the dissenters were in a small minority in nearly all the southern counties of England, notably in Middlesex, Kent, and Sussex. In the metropolis itself, the Protestant dissenters were estimated to form about 10 per cent. of the population.

Number of religious denominations.

Under the Act of 1836, the registrar-general has to keep a list of all the churches and chapels of the various dissenting religious denominations wishing to be "licensed" for the celebration of marriages. The number so entered was, according to the "Thirty-Eighth Annual Report of the Registrar-General," issued in 1877, no less than 122. The following was the reported list of denominations:—

Religious Denominations in England and Wales.

- Advents.
- Apostolics.
- Arminian New Society.
- Baptists, viz.,
    - Baptists.
    - Calvinistic Baptists.
    - General Baptists.
    - General Baptist New Connexion.
    - Old Baptists.
    - Particular Baptists.
    - Presbyterian Baptists.
    - Scotch Baptists.
    - Seventh Day Baptists.
    - Strict Baptists.
    - Union Baptists.
    - Unitarian Baptists.
- Baptized Believers.
- Believers in Christ.
- Bible Christians.
- Bible Defence Association.
- Brethren.
- Calvinists.
- Catholic and Apostolic Church.
- Christadelphians.
- Christians "who object to be otherwise designated."
- Christian Believers.
- Christian Brethren.
- Christian Eliasites.
- Christian Israelites.
- Christian Mission.
- Christian Teetotallers.
- Christian Temperance Men.
- Christian Unionists.
- Church of Christ.
- Church of Progress.
- Church of Scotland.
- Church of the People.
- Countess of Huntingdon's Connexion.
- Disciples in Christ.
- Disciples of Jesus Christ.
- Eastern Orthodox Greek Church.
- Eclectics
- Episcopalian Dissenters.
- Evangelical Unionists.
- Followers of the Lord Jesus Christ.
- Free Catholic Christian Church.
- Free Christian Association.
- Free Christians.
- Free Church.

    Welsh Calvinistic Methodists.
    Wesleyan Methodist Association.
    Wesleyan Reformers.
    Wesleyan Reform Glory Band.
    Wesleyans.
Working Man's Evangelistic Mission Chapels.

The total number of "licensed" churches and chapels belonging to Protestant and other dissenters from the established church was 20,480 on the 31st December, 1875. The number had fallen to 19,486 on the 31st October, 1877.

Wesleyan Methodists and other dissenters.

The numerically most important body of Protestant dissenters is that of Wesleyan Methodists, founded in 1739 by the Rev. John Wesley, clergyman of the Church of England. Subsequently to his death, in 1791, the community split into various subdivisions, of which 13 are enumerated in the preceding list. The largest of these, known simply as Methodists, or Wesleyan Methodists, had on its roll 402,437 members at the end of 1876; and the next largest, the Primitive Methodists, 181,081 members. Of more or less importance, among the other bodies of Protestant dissenters, are the Baptists, split into nearly as many divisions as the Wesleyan Methodists; the Independents, also known as Congregationalists; the Unitarians; and the Moravians. No authentic returns exist regarding the number of persons adhering to any of the minor Protestant creeds reported by the registrar-general as existing in England and Wales.

Number of Roman Catholics.

More numerous than any single body of Protestant dissenters is that of Roman Catholics in England. It is stated by Hallam that in the reign of Queen Elizabeth the Roman Catholics numbered one-third of the entire population; but the effect of the many repressive laws enacted against them was that at the end of the 17th century, when the already referred to religious census of 1699 was taken, the total number was only 27,696, being barely one-half per cent. of the population. It was estimated that the number of Roman Catholics in England had increased to 68,000 in 1767, being about 1 per cent. of the population, and that it stood at 69,400 in 1780, being less than 1 per cent. On the basis of the marriage returns of the registrar-general, the estimated number of Roman Catholics in England and Wales was 284,300 in 1845, or 1·70 per cent. of the population; but within the next six years, when there was a large immigration of Irish, the numbers rapidly rose, and at the end of 1851 the total number of Roman Catholics was calculated at 758,800, being 4·22 of the population. The numbers kept rising till 1854, when there were estimated to be 916,600 Roman Catholics in England and Wales, being 4.94 per cent. of the population; but there was a fall after this year, if not in numbers yet in percentage. The calculated number was 927,500, or 4·61 per cent., in 1861, and 982,000, or 4·62 per cent., in 1866. It is estimated that in the middle of 1877 the number of Roman Catholics in England and Wales had barely reached one million, being a less percentage than in 1866, and that about one-half the number comprised natives of Ireland, with their families. It would thus seem that Roman Catholicism has not been progressive in England for about a quarter of a century. However, the wealth of the body increased very greatly during this period, owing mainly to the secession of many rich persons, of both sexes, to the church, which led to a vast increase of Roman Catholic places of worship. They numbered 616 in 1853, and had risen to 1095 at the end of 1877, with a clergy of 1892. The government of the Roman Catholic Church in England and Wales is under 12 bishops ruling dioceses, and 1 archbishop, head of the "province of Westminster."

Government of the Church of England.

The Established Church of England, to which adhere the majority of the population—the estimated number of members being 13½ millions in the middle of 1877, leaving about 11 millions to all other creeds—was governed, at the end of 1877, by 2 archbishops and 28 bishops, the former at the head of two provinces, and the latter of as many episcopal sees. There were as many as 21 bishoprics at the beginning of the 8th century, which number was thought insufficient at the time, for the Venerable Bede, some years before his death, in 735, exhorted King Egbert to increase the sees by converting many monasteries into cathedrals. However, the advice was not followed; and at the period of the Conquest the number of sees was still 21. During the centuries that elapsed till the Reformation, while the population increased from 1½ to 4 millions of souls, only two new bishoprics were formed, namely, that of Ely in 1109, and that of Carlisle in 1133. In the reign of Henry VIII. it was proposed to establish 20 new dioceses, but only 6 came to be formed, one of which, that of Westminster, had no long existence. Three centuries again elapsed after the Reformation till any more sees were founded, the first new creation being that of Ripon, established in 1836. Eleven years afterwards, in 1847, the bishopric of Manchester was founded; while the lapse of another twenty years saw the establishment of two more bishoprics in those of St. Albans and Truro.

Sees of England and Wales.

The following is a list of the thirty archiepiscopal and episcopal sees of England and Wales—the latter arranged in alphabetical order,—with date of their establishment, and fixed incomes attached to them:—

	Year of Foundation.	Income.
Province of Canterbury.		£
Canterbury (Archbishopric)..	597	15000
Bangor	550	4200
Bath and Wells	909	5000
Chichester	1070	4200
Ely	1109	5200
Exeter	1050	4500
Gloucester and Bristol	1540	5000
Hereford	687	4200
Lichfield	655	4500
Lincoln	1067	5000
Llandaff	550	4200
London	605	10000
Norwich	1091	4500
Oxford	1540	5000
Peterborough	1540	4500
Rochester	602	4200
St. Albans	1877	4500
St. Asaph	550	4200
St. David's	550	4500
Salisbury	1058	5000
Truro	1877	3000
Winchester	635	7000
Worcester	680	5000
Province of York.		
York (Archbishopric)	625	10000
Carlisle	1133	4500
Chester	1540	4500
Durham	990	8000
Manchester	1847	4200
Ripon	1836	4500
Sodor and Man	850	2400

Ecclesiastical Commissioners.

The formerly variable incomes of the archbishops were fixed by a number of statutes arising out of the establishment, in 1832, of a parliamentary "Commission to inquire into the Revenues and Patronage of the Established Church in England and Wales." In 1836 the members of the commission, after having made a close investigation into all the sources of church revenue, were constituted, by Act 6 and 7 William IV. c. 77, a perpetual corporation, under the title of "Ecclesiastical Commissioners for England and Wales," with power to administer the financial affairs of the church, to pay fixed salaries to the principal church dignitaries, to rearrange, under approval of the Queen in council, the boundaries of dioceses and incumbencies, and to take other measures "conducive to the efficiency of the established church, and the best mode of providing for the cure of souls."

Clergy of the Church of England.

In the government of the Church of England, the archbishops and bishops are assisted by 30 deans and 74 archdeacons, the former having fixed incomes, paid by the Ecclesiastical Commissioners, but the latter dependent chiefly on preferments, held independent of their dignity. The more immediate supervision of the parochial clergy, estimated to number about 13,000, is in charge of 610 rural deans, who have no salaries as such, but are entirely dependent on that derived from their preferments, or "livings." The incomes of these vary extremely, being excessively low in many cases, while in others approaching the revenues of the dignitaries of the church. To raise the value of the smallest "livings" has been among the chief labors of the Ecclesiastical Commissioners, and they have been aided in the task by the endeavors of various societies, both lay and clerical, among them that of the "Bishop of London Fund," established in 1864. Foremost among the older organizations stands the "Queen Anne's Bounty," founded in 1703, to increase the incomes of the poorer clergy. The commissioners under the Act of Queen Anne which established the "Bounty" found no less than 5597 livings under £50 per annum in England and Wales; but since that time the number greatly decreased, and although there are no official returns on the subject, it may be estimated that there were not 1000 preferments in the country in 1877 endowed with such small incomes.

Progress of education in the upper and middle classes.

Education.—The spirit of reform which made itself felt in the church by the institution of the Church Inquiry and Ecclesiastical Commissions exhibited itself to a far more vigorous degree during the same period by promoting the cause of education. The work of educational reform began with the upper and middle class schools, and gradually went downwards, till it reached the lowest classes of the population. Parliament began occupying itself with the condition and management of the public schools of England in 1818, when a commission made a report upon them, exposing many evils. Though little action was taken at the time, the work of inquiry continued in various forms, leading to the close inspection of more than 2000 endowed schools. Many of these were compelled to undergo extensive reforms in their mode of teaching, so as no longer to exclude science, art, and modern languages; while the revenues of nearly all of them were regulated, and made to serve larger objects than before. It was the leading aim of the educational reformers in parliament both to deepen and widen education, giving the largest possible number the best possible instruction, and a variety of measures were passed for this purpose. From 1834 direct annual grants were voted, the first of £20,000, for the promotion of education, and in 1839 the Committee of the Privy Council on Education was instituted for the distribution of the money. An Act for the establishment of industrial schools was passed in 1857; and in the same year the universities of Oxford and Cambridge consented to undertake "middle-class examinations" in some of the chief towns of England. These local university examinations began in the summer of 1858, and proved most successful in promoting higher education. It was stimulated no less by an Act passed in 1869, 31 and 32 Vict. c. 118, reforming the government, teaching, and discipline of the seven great public schools of England,—Eton, Harrow, Rugby, Winchester, Shrewsbury, the Charterhouse, and Westminster. This statute greatly widened their field of instruction.

Progress of education among the lower classes.

While these efforts were made to improve the education of the middle and upper classes, the lower classes of the population were not altogether forgotten. Still the achievements in this direction, naturally vastly more difficult, were for a time inconsiderable. The first impulse given towards more determined exertion was by a great educational conference, under the presidency of the Prince Consort, which took place in London in June, 1857, and passed resolutions that were soon echoed all over the land. The first result of the conference was the appointment, in the session of 1858, of a parliamentary commission to inquire into the state of popular education, the report of which was issued, rather tardily, in March, 1861. Close upon the report followed a minute of the Committee of the Privy Council on Education, establishing a revised code of regulations for elementary schools. The code, which was to come into operation on the 1st April, 1862, decreed regular examinations of the pupils, payment by results, evening schools for adults, and various other changes in elementary education, tending to make it more general. But so far from giving satisfaction, the new code raised a storm of opposition, chiefly from the clergy, and had to be altered in some of its most important provisions. In the session of 1870 a statute of the highest importance was passed, which effected little less than a revolution in the state of national education. By this statute, 33 and 34 Vict. c. 75, entitled "An Act to provide for Public Elementary Education in England and Wales," it was ordered that "there shall be provided for every school district a sufficient amount of accommodation in public elementary schools available for all the children resident in such district, for whose elementary education efficient and suitable provision is not otherwise made." It was further enacted that all children attending these "public elementary schools" whose parents were unable, from poverty, to pay anything towards their education, should be admitted free, the expenses so incurred, with all others necessary to carry out the provisions of the Act, to be defrayed out of local taxation. Finally, it was ordered that the whole administration of the new system of public education should be placed under "school boards," elected by the suffrages of all tax-payers, including women, and invested with large powers, among them that of compelling all parents, under severe penalties, to give their children between the ages of five and thirteen the advantages of education. The statute of 1870, proving more beneficial even than expected at the outset, laid a firm basis for universal education.

Public Elementary Education Act of 1870.

Progress of elementary education.

The gradual progress of public elementary education during the course of a quarter of a century is shown in the following table, which gives the total number of schools under Government inspection, the total number of children for whom accommodation was provided, and the average number of children attending the schools, in every fifth scholastic year, ended August 31, from 1850 to 1870, and for each year thereafter to 1876.

Years ended August 31st.	Number of Schools Inspected.	Number of Children who can be Accommodated.	Average Number of Children in Attendance.
1850	1,844	370,948	197,578
1855	3,853	704,495	447,010
1860	6,012	1,158,827	751,325
1865	6,865	1,470,473	901,750
1870	8,986	1,950,641	1,255,083
1871	9,521	2,092,984	1,345,802
1872	10,751	2,397,745	1,445,326
1873	11,911	2,683,541	1,570,741
1874	13,084	2,952,479	1,710,806
1875	14,067	3,229,112	1,863,176
1876	14,875	3,483,789	2,007,732

Parliamentary grants for education.

While the charge for elementary education, under the Act of 1870, chiefly falls upon local rates, there are at the same time large and continually increasing parliamentary grants made, out of imperial funds, for promoting the education of the masses. In 1863 the annual grants for examination and attendance of pupils in elementary schools, under inspection in England and Wales, amounted to only £205; but they rose to £180,303 in 1864, to £376,367 in 1865, to £388,006 in 1866, to £429,885 in 1867, and to £431,594 in 1868. Thus regularly advancing, the grants came to over half a million in 1869, amounting then to £504,286, and over a million in 1875, when they stood at £1,093,378. In 1876 the annual grants for examination and attendance increased to £1,272,495, and in 1877 to £1,415,333.

Denominations of schools.

Denominational Schools.—It appears from parliamentary returns issued in the session of 1874, that at that time, when the school-board system had just begun to take root, the great mass of the pupils of elementary schools under inspection were in institutions belonging to and under the control of the Church of England. The following tabular statement gives the number of pupils present at examination in the elementary schools of England and Wales controlled respectively by the Church of England, the Roman Catholics, the school-boards, and the British, Wesleyan, and all other schools, in the years 1871 to 1873:

Denominations of Schools.	Years ended 31st August.	Total Number of Schools under Inspection.	Total Number of Pupils present at Inspection.
Church of England......	1871	6,724	1,140,118
	1872	7,328	1,172,944
	1873	8,051	1,254,907
Roman Catholic	1871	383	102,471
	1872	464	105,148
	1873	524	111,435
School Boards.	1872	82	11,388
	1873	520	91,262
British, Wesleyan, and all other Schools.......	1871	1,691	352,978
	1872	1,980	379,199
	1873	1,999	389,612
Total	1871	8,798	1,595,567
	1872	9,854	1,668,679
	1873	11,094	1,847,216

Increase of schools under school boards.

Board Schools.—It will be seen that on the 31st of August, 1872, the total number of schools under school boards was not more than 82, with 11,388 pupils present at inspection; and that a year later the number of schools had risen to 520, and that of pupils to 91,262. After this time, with the machinery established by the Act of 1870 getting more and more into working order, and its chief feature, that of compulsion, being gradually applied, the progress of elementary education became very rapid. At the end of August, 1876, there were 1604 schools under school boards in England and Wales, affording accommodation to 556,150 pupils. The total number of school boards at the end of August, 1876, was 1790, of which 123 were in boroughs and 1667 in rural or extra-municipal parishes. There were at the same date 99 boroughs, out of 223, in England and Wales as yet without school boards; still these exceptions included no place with over 50,000 inhabitants. On the 1st of April, 1877, there were 11,221,363 of the total population drawn within the clauses of the Act enforcing the attendance of children at school, so that compulsory education had become the law for about one-half of the population, and it might be calculated that only a few more years would be required to include the whole.

Cost of the school board system and compulsory education.

The total amount received by the school boards of England and Wales in the year ended August 31, 1876, was £2,695,644, of which £1,178,946 came from local rates, and £1,516,698 from loans, the latter raised for the erection of school buildings and other works of a permanent character. The total amount thus borrowed amounted to £5,466,106 at the end of August, 1876, the sum being raised at 3½ per cent. annual interest by the Public Works Loan Commissioners, to be repaid in the course of fifty years from local rates, the pressure upon which is expected to become gradually less as the great work of compulsory education advances towards its completion. The average school board taxation in the whole of England and Wales was 1·87d. per pound sterling in the year 1874–75, and rose to 3·43d. per pound in the year 1875–76.

State of education among adults.

Adult Education.—Though as yet unaffected by the introduction of the system of compulsory education, there is, nevertheless, a vast progress of general instruction visible among the adult generation, as is proved by the constantly growing numbers of persons able to sign their names to the marriage registers. The annual numbers, carefully collected by the registrar of births, deaths, and marriages, as among the most noteworthy tokens of the educational condition of the people, show that while in the quinquennial period 1841–45 there were in England and Wales 32·6 per cent. of men and 48·9 per cent. of women who signed the marriage registers with "marks," being unable to write, the proportion very steadily decreased from period to period, and from year to year, till it had fallen in 1871–75 to 18·5 per cent. in the case of men, and to 25·2 per cent. in the case of women. Thus there was in the thirty-five years from 1841 to 1875 a decrease of 15·5 per cent. in illiterate men and of 25·6 per cent. in illiterate women.

Proportion of persons unable to sign their names to marriage registers.

The proportion of males and females unable to write varies greatly in the several counties of England and in Wales, as will be seen from the following table, which gives the percentage of both sexes who signed the marriage registers with "marks" in the year 1875, according to the 38th annual report of the registrar-general, issued in 1877:—

Counties.	Percentage of Persons signing with "Marks."	
	Men.	Women.
Westmoreland........................	8	8
Surrey........................	9	12

Educational prospects.

Large as seems the proportion of male and female adults still unable to write in England, the registrar-general, in his 38th annual report, published in 1877, arrived at the hopeful calculation that "if instruction increases in future years at the same arithmetical rate as it has done in the years from 1841 to 1875, then all the men will be able to write in 38 years, and all the women in 31 years."

XII. *Crime and Pauperism.*

Number of criminals from 1841 to 1876.

The wide-spread belief that increase of education will lead to a decrease both of crime and pauperism receives some confirmation from the criminal and other statistics of England and Wales for more than a generation, though not to the full extent that might be desired. As regards crime, the decrease of it, while of a fluctuating nature, was much less in proportion than the increase of education, as shown by the number of persons committed for trial before juries in England and Wales and either convicted or acquitted. The following table shows these numbers for every fifth year from 1841 to 1876:—

Years.	Number of Persons Committed for Trial.	Number of Persons Convicted.	Number of Persons Acquitted.
1841	27,760	20,280	7452
1846	25,107	18,144	6935
1851	27,960	21,579	6359
1856	19,437	14.734	4672
1861	18,326	13,879	4423
1866	18,849	14,254	4572
1871	16,269	11,946	4283
1876	16,078	12,195	3841

The small difference between the number of persons convicted and acquitted and the total committed comprised those found to be and detained as insane.

Decrease of crime.

It will be seen from the preceding table that, while the total committals decreased from 27,760 in 1841 to 16,078 in 1876, and the convictions from 20,280 in 1841 to 12,195 in 1876, the downward progress was not regular, but intermittent, fall and rise following each other. Thus there were fewer convictions in the year 1871 than in 1876. The fluctuations in crime and the number of criminals must be referred to complicated causes, chief among them the state of trade and commerce, which, according as they are either flourishing or depressed, greatly influence the condition of welfare of the masses of the population.

Classes of offences.

The classes of offences for which persons were committed for trial in England and Wales, and either convicted or acquitted by juries, in each of the three years from 1871 to 1873, were as follows:—

Classes of Offences.	Years.	Number Committed or Bailed.	Number Convicted.	Number Acquitted or Discharged.
Against the Person	1871	2,175	1,418	735
	1872	2,082	1,403	658
	1873	2,011	1,347	638
Against Property committed with Violence	1871	1,509	1,146	360
	1872	1,325	1,034	290
	1873	1,233	952	279
Against Property committed without Violence	1871	11,265	8,457	2,798
	1872	10,225	7,609	2,604
	1873	10,516	7,968	2,533
Malicious Offences against Property	1871	197	102	94
	1872	162	89	70
	1873	161	81	78
Forgery and Offences against the Currency	1871	483	403	80
	1872	395	336	59
	1873	379	327	52
Other Offences not included in the above Classes	1871	640	420	216
	1872	612	391	220
	1873	593	414	177
Total	1871	16,269	11,946	4,283
	1872	14,801	10,862	3,901
	1873	14,893	11,089	3,757

Numbers and classes of prisoners.

The total number of prisoners confined in the jails of the United Kingdom, under sentence either of juries or of stipendiary and other magistrates, was 220,817 at the end of 1871, and rose to 220 887 in 1872, and 232,362 at the end of 1873. Of the latter total, 165,142 were imprisoned in England and Wales, 33,419 in Scotland, and 33,801 in Ireland. The classes of convicts confined in the prisons of England and Wales—including those imprisoned for debt, and military deserters, under the Mutiny Acts—were as above at the end of the year 1873.

Classes of Prisoners.	Males.	Females.	Total.
CRIMINAL PRISONERS:—			
Convicted (not previously in Custody)	1,105	278	1,383
Committed for Trial	10,194	3,106	13,300
Summarily Convicted	86,250	40,187	126,437
Want of Sureties	2,190	854	3,044
Remanded and Discharged	8,206	3,043	11,249
Total	107,945	47,468	155,413
Debtors and under Civil Process.	6,404	283	6,687
Offenders under Mutiny Act	3,042	......	3,042
Total	117,391	47,751	165,142

Ages of prisoners.

The ages of the 155,413 prisoners—excluding debtors and deserters—in the prisons of England and Wales, at the end of 1873, were as follows:—

Ages of Prisoners.	Males.	Females.	Total.
Under 12 years	1,370	112	1,482
12 and under 21	26,684	8,218	34,902
21 and under 30	32,930	14,710	47,640
30 and under 60	42,528	22,664	65,192
60 Years and upwards	4,167	1,703	5,870
Ages not ascertained	266	61	327
Total	107,945	47,468	155,413

The degree of education of the same 155,413 prisoners was as follows:—

Education of Prisoners.

Education of Prisoners.	Males.	Females.	Total.
Not able to read or write	33,750	18,148	51,898
Proportion per cent. to total.	31·3	38·2	33·4
Able to read, or to read and write imperfectly	69,553	28,559	98,112
Proportion per cent. to total.	64·4	60·2	63·1
Able to read and write well	4,164	485	4,649
Proportion per cent. to total.	3·8	1·0	3·0
Superior Instruction	188	12	200
Proportion per cent. to total.	0·2	......	0·1
Instruction not ascertained	290	264	554
Proportion per cent. to total.	0·3	0·6	0·4
Total	107,945	47,468	155,413

Repeated convictions.

Of the 155,413 prisoners in the prisons of England and Wales at the end of 1873, no less than 61,274, or two-fifths, were old offenders. The number of their previous convictions was as follows:—

Number of Previous Convictions.	Males.	Females.	Total.
Once	15,659	6,182	21,841
Twice	6,938	3,402	10,340
Thrice	3,968	2,227	6,195
Four times	2,725	1,773	4,498
Five times	1,845	1,351	3,196
Six or seven times	2,329	1,820	4,149
Eight to ten times	1,724	2,098	3,822
Above ten times	2,585	4,648	7,233
Total	37,773	23,501	61,274

Criminal population.

The preceding tables show succinctly to what an extent the prisons of England and Wales are filled by what may be called a criminal population, that is, one living regularly by crime. It is a population not very young, nearly one-half of the whole being between the ages of thirty and sixty, and not possessed of any education worth the name,—33·4 per cent., or just one-third of the whole, being unable either to read or write, and 63 per cent. of the whole only able to read, or to read and write imperfectly. Thus more than 96 per cent. of the entire army of prisoners, male and female, belonged, so far as education went, to the dregs of the population; while only a quite inappreciable fraction, expressed by 0·1 per cent., was that of a class described as possessed of "superior instruction."

Expenditure for police.

Police.—Besides the direct cost of prisoners, there are a variety of other expenses connected with their apprehension and conviction, but it would be impossible to give an account of them. Foremost among these expenses stands that for the police, the total charge for which in the year 1873 amounted to £2,567,491. The expenditure was divided as follows among the various classes of the police:—

Classes.	Number.	Expenditure.
County constabulary	9,892	£860,266
Borough police	7,995	620,111
Metropolitan police, including that of dockyards	9,875	1,009,106
City of London police	788	78,008
Total	28,550	£2,567,491

Crime and pauperism.

Pauperism.—There is, as might be expected, an intimate connection between crime and pauperism. At the side of a fixed prison population, steeped in crime, stands a regular workhouse population, sunk in helpless, irretrievable poverty. If far more harmless than the criminal population, the pauper population, on the other hand, is far more numerous, varying between three-quarters of a million and a million. The number of paupers, like that of criminals, kept rising and falling, in alternate waves, during the course of the last generation, under the probable influence of good or bad harvests mainly, and the state of trade, with a general tendency to increase within the first half of the period, and to decrease within the second half. The total number of paupers in the United Kingdom, embracing both those kept in workhouses and those receiving public charity out of doors, was 1,022,540 in 1846, of whom 910,561 were in England and Wales, 69,432 in Scotland, and 42,547 in Ireland. At the end of thirty years, in 1876, the total number of paupers in the United Kingdom had fallen to 906,983, of whom 728,350 were in England and Wales, 100,105 in Scotland, and 78,528 in Ireland. Thus the aggregate decrease within the period was solely due to a decline of pauperism in England, there being an increase of 30,673 paupers in Scotland, and of 35,981 in Ireland.

Number of paupers, 1851 to 1877.

The following table gives the number of paupers, distinguishing "in-door," within workhouses, and "out-door," receiving public relief, in England and Wales, for every fifth year from 1851 to 1871, and each year thereafter to 1877, on the first day of January in every year:—

Years. Jan. 1.	In-door Paupers.	Out-door Paupers.	Total.
1851	110,565	750,328	860,893
1856	125,597	752,170	877,767
1861	130,961	759,462	890,423
1866	137,986	782,358	920,344
1871	165,289	916,637	1,081,926
1872	154,233	823,431	977,664
1873	154,171	736,201	890,372
1874	149,558	679,723	829,281
1875	153,711	661,876	815,587
1876	148,931	600,662	749,593
1877	157,191	571,159	728,350

Number of workhouses.

There were 590 workhouses and "unions" for the relief of paupers in England and Wales on the 1st of January, 1849, and the number gradually rose till it reached 655 in 1864, from which time it remained stationary till 1869, when there was an amalgamation of several poor-law unions. There were 650 work-houses and unions on the 1st of January, 1877.

Able-bodied and adult paupers.

The paupers of 1877 comprised 92,806 returned as "able-bodied," of which number 18,993 received in-door, and 73,813 out-door relief. Of the remaining paupers, 635,544 in number, 138,198 received in-door, and 497,346 out-door relief. Two-thirds of all the paupers were sane adults, the other third comprising children under sixteen years of age, lunatics, and idiots. Among the adult in-door paupers of 1877, the men formed the majority, but the women were nearly three times as numerous as the men among out-door paupers. Aged persons, or widows, deserted wives, and "unmarried mothers" with their children, comprised the great mass of these out-door paupers.

Expenditure for criminals.

Pauperism is far more costly than crime. The total expenditure for criminals in the year 1873 was £585,021, while that for the maintenance of paupers amounted to £7,692,169. The branches of expenditure for criminals in the year 1873, and the average cost of each prisoner, were as follows:—

Branches of Expenditure.	Total Expenditure.	Average Expenditure per Prisoner.		
ORDINARY CHARGES.	£	£	s.	d.
Repairs, furniture, fuel, and light, rent, etc.	112,414	6	7	1
Officers' salaries, allowances, and pensions	236,751	13	7	9
Prisoners' diet, clothing, etc.	153,339	8	13	5
Total	502,504	28	8	3
EXTRAORDINARY CHARGES.				
Repayment of money borrowed, interest, etc., new buildings, additions, and alterations	82,517	4	13	4
Total ordinary and extra-ordinary	585,021	33	1	7

Expenditure for the relief of the poor.

The total amount raised by "poor rates" so-called in England and Wales in the year 1873 was £12,657,943, and the amount expended £12,426,566. But of this expenditure, not more than the sum of £7,692,169, before mentioned, was employed directly for the relief of the poor, the remainder, £4,734,397, going for other payments under the poor-laws, such as police rates, vaccination fees, and disbursements of highway boards. The actual direct expenses for the relief of the poor in the year 1873 were under the following branches:—

	£
Cost of in-door maintenance	1,549,403
Cost of out-door relief	3,279,122
Workhouse loans repaid and interest thereon	272,698
Salaries and rations of officers	893,218
Other expenses connected with the relief of the poor	914,957
Maintenance of lunatics in asylums or licensed houses	780,927
Total	7,690,325

Taxation for pauperism.

The average rate imposed by local taxation for the actual relief of the poor in 1873 was 5s. 11d. in the pound per head of population for the whole of the United Kingdom, while for England and Wales alone it was 6s. 7d. per head of population, for Scotland 5s. 2d., and for Ireland 3s. 4d. Taking the percentage ratio to the whole population, tax-paying and not, the amount was 3s. 3d. per individual for the United Kingdom, while the share for England and Wales was 3s. 8d. per head, for Scotland 3s. 5d., and for Ireland 1s. 4d. per head of population.

Poor-law commissioners and poor-law board.

The enormous cost of pauperism and consequent heavy burden entailed upon taxpayers —deemed the harder as being very unequally distributed, the poorest parishes being the highest assessed—led to many recent legislative attempts to effect a remedy. Under the Poor-Law Amendment Act of 4 and 5 Will. IV. c. 76, passed in 1834, a somewhat complicated administrative machinery was formed for the purpose, receiving the title of "Poor Law Commission;" but it was superseded in 1847 by the statute 10 and 11 Vict. c, 109, which instituted the "Commissioners for administering the Laws for the Relief of the Poor in England and Wales." An Act passed two years after, 12 and 13 Vict. c. 103, abolished alike commissions and commissioners, establishing in their stead, a "a poor-law board," invested with extensive powers, its president having a seat in the Cabinet. Although by the Act itself, and the institution of a new member of the Government, it was sufficiently acknowledged that the question of pauperism had become one of the most momentous of the day, and although its working, under the direction of a very able chief, gave general satisfaction, it was soon found that it was faulty in many respects. It was particularly so in not recognizing that the system of maintaining the poor, having been and remaining entirely local, could not be dissevered from local government in general, and that the necessary reform must be in this direction.

Institution of the Local Government Board.

The admission of this fact led to the passing of another statute, 34 and 35 Vict. c. 70, which obtained the royal assent August 14, 1871, known as the Local Government Board Act. The Act ordered the establishment of a Local Government Board, as a ministerial department, to undertake all the functions of the Poor-Law Board, abolished henceforth, and, moreover, to superintend the execution of all the laws relating to the public health, and to matters connected with local government. The new Local Government Board began its functions in March, 1871, its president holding a seat in the Cabinet.

Annual reports of the board.

Since its institution, the Local Government Board has published annual reports, addressed to parliament, the sixth of which was issued at the end of the session of 1877. Judging by this report, the action of the new system for superintending the relief of the poor has been very successful, there being a considerable decrease of the expenditure for the actual maintenance of paupers. But this was effected entirely by savings in out-door relief. The respective charges for the maintenance of paupers in workhouses and for out-door relief in 1871 and in 1876 were stated as follows in the report:—

Years.	In-door Maintenance.	Out-door Relief.	Total.
	£	£	£
1871	1,524,695	3,663,970	5,188,665
1876	1,534,224	2,760,804	4,295,028
Increase	9,529	....	....
Decrease	....	903,166	893,637

Cost of poor-law administration.

Poor-Law Administration.—According to the sixth annual report of the Local Government Board, the expenditure for the in-door and out-door maintenance of paupers formed little more than half the total cost set down as being "for the relief of the poor." Among the other branches of expenditure were "salaries and rations of poor-law officers," £943,000; "charges for pauper lunatics in asylums," £883,000; and a number of similar disbursements, the total amounting to £3,042,830. It is admitted in the report that, notwithstanding the strictest supervision, the local expenses of administration continue increasing, while the direct cost of maintenance of the poor is decreasing. Thus in 1871, when the actual maintenance of in-door and out-door paupers cost £893,600 more than in 1876, the extra branches of expenditure were £357,000 less.

Pauperism and education.

There cannot be any reasonable doubt that the principal remedy of pauperism must be sought in the general education of the poor. That this is already taking effect, under the salutary working of the Compulsory Education Act of 1870, there are many symptoms. It is stated, in a report of the inspectors of the London board schools, published at the end of 1877, that the order and regularity strictly enforced in their schools not only affect the character of the children, but that of the parents in the most destitute social condition, including paupers receiving out-door relief. "There are indications," says the report, "that the parents are beginning to feel the wholesome influence of the schools. We are assured by teachers in the very lowest neighborhood that there is now much less active opposition to their efforts to improve the children than formerly, and a marked diminution in the violent language and rough conduct which were at one time the invariable accompaniments to a parent's visit to the school." The education of their children, the report goes on to say, is strikingly reflected in a "growing self-respect of the parents," while all things "point unmistakably to a great change for the better, which is being slowly yet surely effected in the homes of the children through the influence of board schools."

XIII. *Hospitals and Charitable Institutions.*

Charity and pauperism.

No country in the world is so rich in charitable institutions of every description as England. The relations between the vast pauperism and the equally vast flow of charity designed to remedy it have been keenly discussed; and while many insist that the latter is simply an offspring of the former, there are others no less confident in maintaining that the abundance of charity has given rise to the very evil it was expected to cure. Probably the truth lies midway between the conflicting arguments. If indigence gave rise to charity, the excess of the latter could scarcely fail in its turn to beget improvidence, and, with it, poverty. There can be little doubt that, in modern times at any rate, the immense multiplication of charitable institutions has served to foster idleness among the lower classes in large towns, and thus has swelled the ranks of hereditary pauperism. Legislation has not remained ignorant of this fact, and hence a large number of laws for regulating the uses and abuses of charity.

Oldest statute on charities.

The oldest of these regulations were made in the same reign which laid the foundation of the poor-law, that of Elizabeth. By the Act of 43 Elizabeth c. 4, passed in 1601, usually known as the Statute of Charitable Uses, a rather wide definition was given of what was considered to be within the realm of charity. It might be used, declared the Act, "for relief of aged, impotent, and poor people; for maintenance of sick and maimed soldiers and mariners; for schools of learning, free schools, and scholars in universities; for repair of bridges, ports, havens, causeways, churches, sea-banks, and highways; for education and preferment of orphans; for relief, stock, or maintenance of houses of correction; for marriages of poor maids; for supportation, aid, and help of young tradesmen, handicraftsmen, and persons decayed; for relief or redemption of prisoners or captives; and for aid or ease of any poor inhabitants concerning payments of fifteens, setting out of soldiers, and other taxes." It is clear from the wording of this statute that, at the time it was made, organized charitable institutions were already numerous in England. In order that they might be well managed, and their funds employed for none but legitimate purposes, the Act ordered that commissioners should be appointed by the lord chancellor, four for each diocese, to act under the bishop, and "inquire by a jury concerning charities." It does not appear that much action was ever taken under the statute, cumbrous in all its prescriptions, and it had fallen into disuse before the middle of the last century, when it was gradually replaced by other legislative enactments.

Records of charitable institutions.

No general record of charitable institutions is known to have existed until the close of the 18th century, when the subject came to occupy the serious attention of parliament. It manifested itself chiefly in the passing of a statute, 26 Geo. III. c. 58, generally called the Gilbert Act, which gave orders "for procuring, upon oath, returns of all charitable donations for the benefit of poor persons in the several parishes in England." The returns obtained under this Act were examined and reported on by a committee of the House of Commons, which sat in 1786 and 1788, when it appeared that out of 13,000 parishes and townships in England and Wales, only 14 had omitted reporting their charities. The aggregate annual income of those reported upon amounted to £528,710, but it was generally held that this sum was a gross understatement. Consequently, there was more legislation, though at considerable intervals, on the subject of charities. Under an Act of 52 George III. c. 102, passed in 1812, stringent regulations were laid down for ascertaining the nature and income of all the charitable institutions in England; but the Act was never properly enforced, and remained to all intents and purposes a dead letter. More effective, although limited in scope, was an Act of 58 George III. c. 91, passed in 1818, which ordered an inquiry into the educational charities of England. It was this statute which first instituted the "Charity Commissioners for England and Wales."

The board of charity commissioners.

The actual functions of this board, in superintending all charities, and making annual reports upon them to parliament, were defined by the Charitable Trusts Act of 1853, to which amendments were passed in 1855, in 1860, and in 1869. By these statutes, the "Charity Commissioners for England and Wales" are invested with great powers, some of them distinctly judicial in their nature, and the rest of an administrative character. They may compel the trustees and administrators of all endowed charitable institutions to keep full accounts of their receipts and disbursements, and to forward them every year; and they may likewise order special inquiries into the circumstance of individual charities, and enforce the production of all required information. Possessed of such powers, the commissioners have been enabled to publish a number of valuable annual reports, beginning with the year 1852, on the number and character of the net-work of charitable institutions spread all over England, tending to alleviate misery and to promote greater welfare, or at least designed to do so. Still these reports are far from giving a complete picture of the vast extent of organized charity, since the action of the Charity Commissioners does not embrace any but endowed charities, and not all even of this class. Specially exempted from the operations of the Charitable Trusts Act of 1853, and its subsequent amendments, are the charities of the universities and their colleges, those of Eton and Winchester, of the various cathedral foundations, of all friendly and benefit societies, and of all institutions wholly maintained by voluntary contributions. Among these and other exemptions fall a number of charitable institutions as important of their kind as ancient in origin—the Hospitals.

Origin of hospitals.

There can be little doubt that hospitals were, if not the very oldest, at least among the most ancient, of English charitable institutions. The earliest of these establishments probably grew up in the time of the crusades, or soon after, necessitated by the spread of new diseases, introduced by the knights and their followers returning from the East. How terrible were the ravages made by some of these diseases, such as leprosy, is shown by the fact that there were counted in France, in the year 1225, upwards of 2000 hospitals, going by the distinctive name of "leprosoria." England must have suffered, as well as France, from the influx of the infectious maladies from the same source, although the English crusaders were much less numerous, and many of them belonged to a better class. Neither in France nor in England any trace is left of the "leprosoria" of the 13th century, all the existing hospitals being of more modern foundation.

The oldest English hospital.

The most ancient in the list of English hospitals is that of St. Bartholomew, London, which had its origin in a priory of the same name, founded by Rahere, a minstrel of King Henry II., about the year 1100. A quarter of a century later, Rahere obtained from the king the grant of a piece of waste ground, adjoining the monastery, where he built and endowed a hospital "for a master, brethren, and sisters, and for the entertainment of poor, diseased people till they get well." At the dissolution of the monasteries, in the reign of Henry VIII., St. Bartholomew contained 100 beds, with one physician and three surgeons. The hospital was refounded, on a new basis, in 1544, and incorporated by charter in 1546. St. Bartholomew, on account of its age no less than of the excellency of its medical staff, continues to stand in the foremost rank of English hospitals, as of the endowed charities of the country in general. Its average annual income, in recent years, amounted to about £40,000, derived mainly from rents and funded property. In 1876 St. Bartholomew's Hospital had 5672 in-patients and 19,576 out-patients, together with 153,905 other patients attending for temporary medical and surgical attendance, thus affording relief to 179,153 persons in the course of the year.

The five royal hospitals.
